Abstract The nanoscale elastic-plastic characteristics of the C plane of sapphire single crystal were studied by ultra-low nanoindentation loads with a Berkovich indenter within the indentation depth less than 60 nm. The smaller the loading rate is, the greater the corresponding critical pop-in loads and the width of pop-in extension become. It is shown that hardness obviously exhibits the indentation size effect (ISE), which is 46.7 ± 15 GPa at the ISE region and is equal to 27.5 ± 2 GPa at the non-ISE region. The indentation modulus of the C plane decreases with increasing the indentation depth and equals 420.6 ± 20 GPa at the steady-state when the indentation depth exceeds 60 nm. Based on the Schmidt law, Hertzian contact theory and crystallography, the possibilities of activation of primary slip systems indented on the C surface and the distributions of critical resolved shear stresses on the slip plane were analyzed.

1. Introduction

Sapphire ($\alpha$-Al$_2$O$_3$) is an important crystal material due to its high hardness, chemical inertness, superior mechanical performance, and thermodynamic stability\textsuperscript{1-3}. Generally, sapphire is brittle and its brittle-to-ductile transition temperature is ~1373 K. However, the plastic deformation of sapphire crystals may occur under low loads at room temperature\textsuperscript{4}. Recently, the evaluation of the initial stages of plasticity and elastic-plastic deformation properties of sapphire with different surface orientations at room temperature have been extensively investigated by nanoindentation tests\textsuperscript{4-12}. These studies show that single and/or multiple displacement discontinuity (pop-in) events during loading are found to distinguish between the fully elastic and the elastic plastic regimes, associated with the nucleation of dislocations. As we know, the C plane (0001) of sapphire is generally selected as a calibration medium during nanoindentation\textsuperscript{13} and substrate in the preparation of many kinds of functional thin film/substrate systems\textsuperscript{14, 15}. It is necessary to study the mechanical properties of the C plane under different size scales and measurement conditions. Although many studies have been done on elastic plastic behaviors of the C plane by micro-/nano-indentation with relatively large Berkovich or spherical indenters, the interpretation of indentation results obtained at room temperature is not straightforward because these indentation measurements are strongly affected by factors such as the anisotropic elasticity of sapphire, surface roughness, the radius and shape of indenter tip, loading rate and indentation depth\textsuperscript{4-8}. In this paper, the nanoscale elastic/plastic deformation and mechanical properties of the C plane have been systematically studied by depth-sensing nanoindentation experiments at
room temperature. The contact area function and radius of the Berkovich tip were carefully calibrated under very small indentation depth by nanoindentation and atomic force microscopy (AFM) instruments. The mechanical properties and surface deformation mechanism of sapphire crystal indented on the C plane were analyzed under the anisotropic elastic characteristic and small indentation depth. The critical resolved shear stresses (CRSS) at slip planes were evaluated with the aid of the Hertzian contact theory, compared with the corresponding theoretical shear strength. The experimental and analytical results would greatly shed light on the understanding of the nanoscale deformation features of sapphire crystal indented on the C plane.

2. Experimental

The samples of sapphire crystal were obtained from Semiconductor Wafer, Inc in Taiwan. As specified by the manufacturer, these single crystals were C-axis oriented, double-side polished, and free from defects and residual stress with a root-mean-square roughness < 0.2 nm. Our X-ray diffraction θ-2θ measurements confirmed that the samples were high quality single crystals. All nanoindentation experiments were conducted using an indenter (Triboscope, Hysitron Inc.) equipped with a three-sided pyramidal Berkovich diamond tip and an in-situ scanning probe microscopy (SPM) at room temperature. The force and displacement sensitivities of the instrument are 100 nN and 0.2 nm, respectively. Indentations were performed under a variety of peak loads in the range of 0.7 to 8 mN. For all nanoindentation tests, the loading and unloading times were 20 s and holding time was set as 10 s at the peak indent loads, which resulted in a series of different loading rates ranging from 0.035 to 0.4 mN/s. To obtain
reliable data, each cycle was repeated 8 times. The thermal drift was kept below ± 0.05 nm/s for all indentations.

3. Results and discussion

3.1 Calibration of indenter tip radius

Prior to nanoindentation tests, the contact area function and effective indenter tip radius should be carefully calibrated by using a standard sample such as fused quartz. As shown in Fig. 1, the experimental data are fitted by the area function

\[ A = C_0 h_c^2 + C_1 h_c^{1/2} + C_2 h_c^{1/4} + \cdots + C_8 h_c^{1/128} \]  

where \( C_0, C_1, \cdots C_8 \) are constants, and \( h_c \) is the contact depth. The lead term describes a perfect Berkovich indenter; others represent deviations from the Berkovich geometry due to blunting at the tip. These coefficients should be fitted by the \( A \) and \( h_c \) data based on the relevant indentation depth range. In this work, we focus on the two different ranges of 10 – 100 nm and 100 – 500 nm indentation depths. Under the small range of 10 – 100 nm, the Berkovich tip is generally regarded as spherical or parabola revolution. The relationship between \( A \) and \( h_c \) can be well described by a simple two-parameter relationship, \( A = C_0 h_c^2 + C_1 h_c \). In the limit of \( h_c \ll R \) (here \( R \) is the radius of indenter tip), the relationship can approximately reduce to \( A = 2\pi Rh_c \). As shown in Fig. 1, for \( h_c < 60 \) nm, the relationship was found to be \( A = 25.8h_c^2 + 752.7h_c \) for our Berkovich indenter, where the units of \( A \) and \( h_c \) are nm² and nm, respectively. Consequently, the tip radius \( R \) obtained from the second term, \( C_1 = 2\pi R \), is equal to 120 ± 5 nm. However, for a relative large indentation range of 100 – 500 nm, we must re-calibrate the tip area function. For the indentation depth of sapphire single crystal, two different tip area functions are
chosen to analyze the indentation data.

To verify the tip radius, the three-dimensional geometry of an instrumented indenter was carefully measured by atomic force microscopy (AFM). The AFM image data can be obtained by scanning the Berkovich tip apex. For each AFM image, scanning is along the orthogonal directions of cross-sections through the apex of indenter, which are parallel to the \( x \)-and \( y \)-directions, respectively, as shown in Fig. 2(a). A parabolic curve was fitted to the near-apex region of the cross-sectional data, as shown in Fig. 2(b) and \( R \) was determined from the parabolic equation at the apex location. To discern the difference\(^{19}\), four curves are dissociated by adjusting the values of relative vertical distance in Fig. 2(b). It is shown that the average value of the tip radius, \( R = 130 \pm 10 \) nm obtained by AFM, is slightly larger than that from nanoindentation measurements. In the subsequent analysis, \( R \) is regarded as about 125 nm.

3.2 Characteristics of load-displacement curves

Figure 3 shows the total of the 8 representative load-displacement (\( P-h \)) curves of the indented C plane during nanoindentation. It is obvious that multiple displacement discontinuities or pop-in events occur during loading. The load corresponding to the first pop-in event is defined as the critical indentation load \( P_{cr} \), which varies in the range of 0.40 to 0.62 mN (see inset in Fig. 3). The width of pop-in extension is denoted with \( \Delta h_{cr} \) due to the slip of activated dislocation. The pop-in phenomena are consistent with the earliest observations reported by Page and Tymiak et al.\(^4,5,7\). However, \( P_{cr} \) in their studies were much higher than \( P_{cr} \) in our work, which may ascribe to the radius magnitude of indenter tip. It is also found the fluctuation phenomena of the \( P_{cr} \) among
these pop-in events, which is similar to other experimental results\(^{20,21}\). The reason may be due to the effects of thermal drift and surface roughness under the condition of ultra-low loads.

In nanoindentation tests, the loading rate \( \dot{P} \) ranges from 0.035 to 0.4 mN/s. The relationships of the average \( P_{cr} \), average pop-in extension width \( \Delta h_{cr} \), and \( \dot{P} \) for the C plane are shown in Fig. 4. It is seen that \( P_{cr} \) and \( \Delta h_{cr} \) decrease gradually with increasing \( \dot{P} \) with the range from 0.035 to 0.35 mN/s. It is more obvious under the lower loading rate and smaller indentation depth of \( h < 60 \) nm. When \( \dot{P} \) is small, the slip plane of the primary slip system in sapphire crystal has enough time to be stressed and activated, which results in the large width of pop-in extension \( \Delta h_{cr} \), i.e., the burst displacement. If \( \dot{P} \) rapidly increases, however, the elastic and elastic-plastic transitions of sapphire crystal are too fast to adequately slip or twinning. Thus, \( P_{cr} \) and \( \Delta h_{cr} \) may decrease, and even the pop-in phenomena may disappear. Under the large \( \dot{P} \), Tymiak et al. found that the influence of loading rate was not clear for the C plane during nanoindentation with a 100 nm cube corner indenter tip\(^4\). Therefore, the loading rate and indentation depth range have an important influence on the elastic-plastic deformation of sapphire crystal, especially at nanoscales.

In this paper, we would emphasize on the first pop-in phenomenon of the C plane corresponded to the initial elastic plastic transition of sapphire crystal. After indentation, to clarify the surface morphology of residual impression indented by the Berkovich indenter with a peak load of 1 mN, the in-situ SPM observations of nanoindentation instrument are performed, as shown in Fig. 5, which may provide additional insight into
the mechanisms of indentation-induced deformation. It is not observed from Figs. 5(a) and (b) apparent linear surface feature and cracking near the vicinity of the impression surface after the elastic plastic transition of the C plane. The results are similar to the previous observations obtained by conical indenter. The different linear topography profiles across the center of the impression are shown in Fig. 5(c). It is demonstrated that, even for hard and brittle sapphire, there are slight pile-ups with the relative high amplitude (see Fig. 5(c)). The maximum height of pile-ups is about 1.5 nm. The maximum indentation depth determined from these profiles is about 9.4 nm, which is close to the residual impression depth (10.2 nm) recorded by the corresponding load-displacement curve of 1 mN peak load in Fig. 3. The subtle discrepancy may be due to the finite curvature radius of the scanning probe tip and elastic recovery in unloading, which prevents it from reaching the impression bottom.

3.3 Hardness and Indentation modulus

Based on the Oliver-Pharr method, the hardness $H$ of the C plane and the effective indentation modulus $E_r$ of the indentation system can be directly obtained from nanoindentation instrument. It is found that $H$ displays strong indent size effect (ISE) within the range of $h < 60$ nm, i.e. the value decreases with the increase of indentation depth, as shown in Fig. 6(a). At the ISE region, the average $H$ is $46.7 \pm 15$ GPa, as shown with the red square. At the load-independent hardness region, the range of $H$ equals $27.5 \pm 2$ GPa, which is in good agreement with the result of $28.9 \pm 2.3$ GPa. The indentation modulus $E_{\text{specimen}}$ of the C plane can be determined by contact mechanics. Here, $1/E_r = 1/E_{\text{specimen}} + (1-v_i^2)/E_i$, where $E_i = 1141$ GPa and $v_i = 0.07$ are
Young’s modulus and Poisson’s ratio of the Berkovich diamond indenter\textsuperscript{13, 18, 24}. It is seen in Fig. 6(b) that the values of $E_{\text{specimen}}$ are closely related to the indentation depth. Similar experimental phenomena have also been reported in previous studies\textsuperscript{25, 26}. When $h$ is less than 60 nm, $E_{\text{specimen}}$ decreases with the increase of $h$ and is equal to 493.2 ± 50 GPa, as indicated by the red dots in Fig. 6(b). If $h$ exceeds to 60 nm, $E_{\text{specimen}}$ gradually goes into saturation and is equal to 420.6 ± 20 GPa. For sapphire with the trigonal symmetry, there are six independent elastic constants. These elastic constants were determined as $C_{11} = 496.72$, $C_{12} = 163.4$, $C_{13} = 110.73$, $C_{33} = 497.98$, $C_{14} = -23.49$ and $C_{44} = 148$ GPa\textsuperscript{13}. The Poisson’s ratio, shear modulus $G$ and Young’s modulus $E_{(0001)}$ along the C-axis relevant to indentation is given, respectively, by $v = C_{13} / (C_{11} + C_{12})$, $G = (C_{11} - C_{12}) / 2$ and $E_{(0001)} = C_{33} - 2vC_{13}$ under purely elastic deformation\textsuperscript{27}. So, the anisotropic elasticity formula gives $E_{(0001)} = 461.0$ GPa, which is consistent with the experimental results obtained in the range of $h < 60$ nm. Under the anisotropic elastic contact, Swadener et al. obtained that the indentation modulus of the C plane of single-crystal sapphire was about 431 GPa\textsuperscript{13}. The measured result by Oliver et al. was 441 ± 4.7 GPa for (0001) sapphire during nanoindentation with a Berkovich indenter\textsuperscript{18}. Ruppi et al. reported the value of hardness of $\alpha$-Al$_2$O$_3$ with (0001) texture was 444 ± 20.7 GPa\textsuperscript{22}. Our results in the range of $h > 60$ nm agree well with that form these works.

3.4 Elastic to elastic-plastic transition analysis

The purely elastic and elastic-plastic transitions of the C plane are shown in Fig. 7. To identify the purely elastic behavior of the C plane, more nanoindentation tests with
the maximum load of 0.3 and 0.5 mN were performed below \( P_{cr} \) (about 0.6 mN), respectively. It is clearly observed that the loading and unloading parts of both load-displacement curves are perfectly superimposed in inset of Fig. 7. It strongly implies that all the samples deform elastically and no residual deformation occurs. It also indicates that the nanoindentation tests have good reproducibility in our tests. Therefore, the deformation can be regarded as perfectly elastic up to a load of 0.5 mN. This is also supported by the SPM imaging after indentation, which shows that the sample surface underneath the indenter is damage-free. In these tests, the maximum nanoindentation depth is 19 nm that is less than 30 nm, so the Berkovich indenter can be approximately considered as spherical. The ideal elastic response of the C plane can be described as \( P = (4/3)R^{1/2}E_r h^{3/2} \) by Hertzian contact theory, where \( P \) is indentation load, \( h \) is indentation depth and \( R \) is the radius of spherical indenter tip. A Hertzian equation \( P = 0.00576738h^{1.5} \) can be fitted from the indentation data and the relevant curve is shown with red line (see inset), where the units of load \( P \) and displacement \( h \) are mN and nm, respectively. On the other hand, the coefficient of the equation can be used to verify the calibrated tip radius above. In the purely elastic tests, \( E_r \) is about 387 GPa, and \( R \) can be deduced as 125 ± 2 nm, which is consistent with the calibration results in Section 3.1 by the standard fused quartz sample and AFM measurements. To further examine the transition from the elastic to elastic-plastic (pop-in) features of the C plane, other nanoindentation tests at the peak load of 0.7 and 0.8 mN were conducted, respectively, as shown in Fig. 7. Both two peak loads are slightly larger than \( P_{cr} \) (about 0.6 mN). It is obvious that the typical displacement
discontinuities occur during loading. Moreover, the above fitted Hertzian equation is utilized to describe the elastic behavior and elastic-plastic transition. It is interesting to see that the experimental measurement and theoretical prediction fit well before pop-in events.

3.5 Evaluation of slip system and CRSS at slip plane

It is commonly accepted that the initial pop-in event occurs when shear stress acting in the slip direction reaches a critical value, which induces dislocations to move across the slip plane. Generally, the critical shear stress is inversely proportional to the interplanar distance $d_{hkl}$ of the corresponding slip plane because the greater $d_{hkl}$ is, the weaker is the binding force between atoms. It results in the smaller CRSS of a slip system. On the other hand, for hexagonal close packed (hcp) crystal such as sapphire, their elastic-plastic deformations are usually affected by $d_{hkl}$, the ratio of $c/a$, loading rate, testing temperature, applied stress and orientation. Compared with the analysis of slip mechanisms of cubic close-packed crystals, the slip and twinning of hcp crystals are more complicated and usually analyzed with the aid of multiple methods, such as transmission electron microscopy$^{29, 30}$, high resolution electron microscope and numerical simulations$^{9, 12}$. Under the action of an applied stress along the [0001] axis, the competition of different slip systems in sapphire crystal would be activated, depending on the value of the critical resolved shear stress (CRSS) and the orientation of slip systems with respect to the external stress. The onset of elastic-plastic transition of the C plane is mainly attributed to slip under such a small indentation load and depth$^4$. Based on the reported prevalent slip systems in sapphire, the possibility of activation of
the primary slip system in sapphire single crystal was estimated when indenting on the C plane. The similar method applied in the yield point analysis of the cubic crystal was reported by Gerberich et al.\textsuperscript{31} In the previous works, the families of slip systems of sapphire crystal were determined by TEM observations\textsuperscript{30, 32, 33} and mainly listed as follows: basal slip \((0001)<11\overline{2}0>\), prism slip \(\{11\overline{2}0\}<\overline{1}00>\) and pyramidal slips \(\{2\overline{1}\overline{3}\}<\overline{1}01>\), \(\{2\overline{1}\overline{3}\}<01\overline{1}0>\), \(\{10\overline{1}1\}<\overline{1}2\overline{1}0>\), \(\{10\overline{1}1\}<1\overline{1}01>\), \(\{2\overline{1}\overline{2}\}<01\overline{1}0>\) and \(\{01\overline{2}\}<\overline{2}021>\). The analysis by the Schmidt law indicates that, among these slip systems, only the Schmidt factors of three pyramidal slips, \(\{2\overline{1}\overline{3}\}<\overline{1}01>\), \(\{10\overline{1}1\}<1\overline{1}01>\) and \(\{01\overline{2}\}<\overline{2}021>\), are non-zero and equal to 0.407, 0.255 and 0.332, respectively. The inclined angles between the three pyramidal slip planes and indented \((0001)\) surface are 61.2°, 72.4° and 57.6°, respectively. Their corresponding \(d_{\{2\overline{1}\overline{3}\}}\), \(d_{\{10\overline{1}1\}}\) and \(d_{\{01\overline{2}\}}\) are 0.2087, 0.3932 and 0.3483 nm, respectively. Therefore, when indenting on the C plane of sapphire crystal, the primary slip system may be due to the competition between pyramidal slips \(\{2\overline{1}\overline{3}\}<\overline{1}01>\) and \(\{01\overline{2}\}<\overline{2}021>\). To further discuss the possible slip deformation, one has to refer to the resolved shear stress of the two families of crystal planes \(\{2\overline{1}\overline{3}\}\) and \(\{01\overline{2}\}\) during the elastic-plastic transition of the C plane. Considering the hexagonal symmetry of hexagonal sapphire crystals, the Miller-Bravais system \((a, a, c)\) is generally transformed into the Cartesian coordinate system \((x_1, x_2, x_3)\), in which \([2\overline{1}\overline{0}0]\), \([01\overline{1}0]\) and \([0001]\) are a set of Cartesian axes \(x_1\), \(x_2\) and \(x_3\), respectively. In addition, their corresponding stress fields near the indented \((0001)\) surface can be estimated by the Hertzian contact theory\textsuperscript{33}. After a series of stress alternations in the Cartesian coordinate system, the resolved shear stress distributions of
the presumptive two slip planes \((01\bar{T}2)\) and \((2\bar{T}T3)\) were estimated, as shown in Figs. 8(a) and (b), which were calculated by experimental parameters at small size scale such as, \(P_{cr} = 0.613\) mN, \(R = 125\) nm, and \(E_r = 328.9\) GPa. In Fig. 8, we have the average pressure \(P_m = (16P\varepsilon_i^2 / 9\pi R^3)^{1/3}\) and the contact radius \(a = (3PR / 4E_r)^{1/3}\). For the slip plane \((01\bar{T}2)\), the maximum shear stress of 28.8 GPa locates underneath the indenter of coordinates \((r/a = 0, z/a = -0.405)\). For the slip plane \((2\bar{T}T3)\), the maximum shear stress of 30.0 GPa locates underneath the indenter of coordinates \((r/a = 0.303, z/a = -0.405)\). Previous studies on single crystal and amorphous materials showed that the initial plastic deformation under nanoindentation happens at the shear stress in the absence of dislocations, where \(G\) is the shear modulus\(^{24}\). For the C plane of sapphire indented along the C axis, the above analysis shows \(G = 167\) GPa. Generally, \(G\) is about 150 – 170 GPa in other available experimental data\(^{29,34}\). The two maximum critical resolved shear stresses above at the assumed slip planes agree well with the theoretical shear strength, \(\tau_{th} \approx G / 2\pi = 26.5\) GPa. The results also indicate that the ratio of \(\frac{\tau_{(01\bar{T}2)\ critical}}{P_m}\) is approximately equal to \(\frac{\tau_{(2\bar{T}T3)\ critical}}{P_m}\), but \(d_{(012)}\) is 1.7 times larger than \(d_{(2\bar{T}3)}\). Therefore, when indenting on the C plane, the primary slip system was estimated as the pyramidal slip \(\{01\bar{T}2\}<02(21)\). While the \(\{2\bar{T}T3\}<T101\) is considered as a potentially important slip system. With the increase of indentation loads, other slip and subsequent twinning systems may be operated. The movement and interaction of different dislocations would become more complicated.

4. Conclusions

Nanoscale multiple pop-in phenomena of the C plane of sapphire single crystal were clearly observed by nanoindentation contacts at room temperature. The
corresponding mechanical properties, stress distribution and deformation mechanism were discussed by the Oliver-Pharr method and Hertzian contact theory, respectively. Main conclusions can be summarized as follows. The critical pop-in loads for the C plane gradually decrease as loading rates increase within the nanoscale indentation depth range. The smaller the loading rate is, the greater the width of pop-in extension becomes. Hardness for the C plane obviously exhibits the indentation size effect. The average \( H \) is 46.7 ± 15 GPa at the ISE region and is equal to 27.5 ± 2 GPa at the non-ISE region. The indentation modulus for the C plane decreases with the increase of indentation depth. The steady-state average value of indentation modulus is equal to 420.6 ± 20 GPa when \( h \) exceeds to 60 nm. According to the reported prevalent slip systems in sapphire single crystal, the possibility of primary slip systems were analyzed and estimated as the pyramidal slip \{01\(\overline{1}2\}\(\overline{2}0\overline{2}1\) based on the Schmidt law, Hertzian contact theory and crystallography. The contour of critical resolved shear stresses at slip planes were obtained by the Hertzian contact theory.
