27  
28 **Abstract**

29  
30 Taxonomic identification of archaeological fish bones provides important insights  
31 into the subsistence practices of ancient coastal peoples. However, it can be difficult  
32 to execute robust morphological identification of fish bones from species-rich fossil  
33 assemblages, especially from post-cranial material with few distinguishing features.  
34 Fragmentation, weathering and burning further impede taxonomic identification,  
35 resulting in large numbers of unidentifiable bones from archaeological sites. This  
36 limitation can be somewhat mitigated by taking an ancient DNA (aDNA) bulk-bone  
37 metabarcoding (BBM) approach to faunal identification, where DNA from non-  
38 diagnostic bone fragments is extracted and sequenced in parallel. However, a large  
39 proportion of fishing communities (both past and present) live in tropical regions that  
40 have sub-optimal conditions for long-term aDNA preservation. To date, the BBM  
41 method has never been applied to fish bones before, or to fossils excavated from an  
42 exposed context within a tropical climate. Here, we demonstrate that morphologically  
43 indistinct bulk fish bone from the tropics can be identified by sequencing aDNA  
44 extracted from 100-300 ya archaeological midden material in southwest Madagascar.  
45 Despite the biases of the approach, we rapidly obtained family, genus, and species-  
46 level assemblage information, and used this to describe a subset of the ichthyofauna  
47 exploited by an 18<sup>th</sup> century fishing community. We identified 23 families of fish,  
48 including benthic, pelagic, and coral-dwelling fishes, suggesting a reliance on a  
49 variety of marine and brackish habitats. When possible, BBM should be used  
50 alongside osteological approaches to address the limitations of both; however, this

51 study highlights how genetic methods can nevertheless be a valuable tool for helping  
52 resolve faunal assemblages when morphological identification is hindered by  
53 taphonomic processes, lack of adequate comparative collections, and time constraints,  
54 and can provide a temporal perspective on fish biodiversity in the context of  
55 accelerated exploitation of the marine environment.

## 56 57 **1 Introduction**

58  
59 The identification of archaeological fish bone offers important insights into the  
60 subsistence practices of ancient fishing communities. Fish are a staple food for coastal  
61 peoples throughout the world; modern estimates suggest that approximately 60% of  
62 the global population lives within 100 km of the coast (Erlandson and Rick 2008). As  
63 such, there is tremendous potential for archaeological data and interpretations to  
64 provide a long-term perspective that can inform present-day marine resource  
65 management and conservation policies (Braje 2010, Braje *et al.* 2015, Labridés and  
66 Weisler 2016, Speller *et al.* 2012). Fine-grained archaeological investigations of  
67 resource exploitation patterns are especially important because human arrival in many  
68 regions of the world has been correlated with an increase in faunal extinctions,  
69 implying that over-exploitation of local fauna has contributed to significant loss of  
70 biodiversity (Braje and Erlandson 2013). The coincidence of human colonisation and  
71 declines in floral and faunal diversity is particularly acute in island contexts (Rick *et al.*  
72 *et al.* 2013). One example is Madagascar, which—although still considered a  
73 biodiversity ‘hotspot’ (Myers *et al.* 2000)—has undergone a significant loss of  
74 biodiversity over the last two thousand years that has long been thought to coincide  
75 with human arrival on the island (de la Bâthie 1921, Humbert 1927). However, many  
76 questions remain as to the timing of environmental change in Madagascar and the role  
77 early communities played in shaping the island’s land and seascapes, particularly  
78 given the challenges of investigating early forager sites (Douglass and Zinke 2015).  
79 Furthermore, disentangling anthropogenic and climatic drivers of environmental  
80 change remains a central research concern in Madagascar, since the island’s climate  
81 and environment were in constant flux well before human colonisation (Dewar and  
82 Richard 2007, Douglass and Zinke 2015). Moreover, despite the fact that Madagascar  
83 is an island, the historical ecology of Madagascar’s marine and coastal environment  
84 has received little research attention. Instead, as is the case in other parts of the world  
85 (Erlandson and Rick 2008), far more archaeological and paleontological work has  
86 been directed at understanding anthropogenic impacts on terrestrial ecologies.

87  
88 Determining how humans impacted the marine environment of Madagascar during  
89 the Holocene relies on a thorough understanding of the marine taxa that were targeted  
90 by ancient communities. Burnt or modified fish bone, or fish bones found in cultural  
91 deposits, are good gauges of direct human interaction with marine biota. As such, the  
92 identification of archaeological fish bone is essential to uncovering marine prey  
93 targets; to date, few studies comprehensively achieve this (Labridés and Weisler  
94 2016), largely because of the limitations to morphological identification. The  
95 identification of fish bone predominantly relies on the examination of size range and  
96 diagnostic osteological features (Labridés and Weisler 2015). Cranial elements,  
97 such as teeth, are particularly important in refining taxonomic identification.  
98 However, the cranium and teeth generally make up a small proportion of the overall  
99 number of bones recovered from archaeological deposits (Yang *et al.* 2004); for each  
100 cranium, there may be over three times as many post-cranial elements (Jones 2009),

101 including vertebrae, ribs, spines, and rays. Articulated specimens are even rarer  
102 because fish remains are fragile and susceptible to damage during food preparation,  
103 cooking, and consumption, as well as to post-depositional weathering (Collins 2010).  
104 Vertebrae and ribs of many fish species are often difficult, if not impossible, to  
105 distinguish from one another as they display little variation between species  
106 (Teletchea 2009). To complicate matters further, many fish exhibit different  
107 morphology throughout their development from juvenile to adult, and can also display  
108 high intraspecific morphological variability, sexual dimorphism (Teletchea 2009), and  
109 phenotypic plasticity (Lambrides and Weisler 2015). Depositional bias, taphonomy,  
110 and lack of diagnostic features hinder morphological taxonomic identifications in  
111 many archaeological assemblages of fish bones, and often result in large numbers of  
112 unidentified remains.

113

114 Ancient DNA (aDNA) is a complementary method to the study of faunal remains, as  
115 it does not rely on the preservation of diagnostic morphological features. However, in  
116 Sub-Saharan African contexts, studies of archaeological aDNA are rare, despite the  
117 potential for aDNA analyses to complement traditional approaches to questions of  
118 human-environment interaction (Campana *et al.* 2013, Gifford-Gonzalez 2013). For  
119 fish, DNA reference collections represent a large portion of fish diversity, and DNA  
120 analysis has been used to discriminate cryptic species and morphotypes; for example,  
121 the genus *Schindleria* consists of 21 genetically distinct but morphologically cryptic  
122 species (Kon *et al.* 2007), while the morphologically different *Eumicrotremus*  
123 *spinusus* and *E. eggvini* constitute a single species (Byrkjedal *et al.* 2007). Ancient  
124 DNA has also proved to be a useful tool in studies of archaeological fish assemblages  
125 (Campana *et al.* 2013), albeit in a relatively small number of studies (Teletchea 2009):  
126 in a literature search, only approximately 2.5% of articles published on archaeological  
127 aDNA relate to fish. However, the studies that have been published demonstrate the  
128 value of such an approach in garnering important information about species diversity  
129 and distribution in the past (Cannon and Yang 2006, Grier *et al.* 2013, Speller *et al.*  
130 2005, 2013, Yang *et al.* 2004), and the economic importance of different fish taxa to  
131 ancient communities (Nikulina and Schmöelcke 2015).

132

133 The infrequent use of aDNA techniques in the analysis of archaeological fish  
134 assemblages may be due to the fact that fish bones are often too small and numerous  
135 to warrant the high cost of individual DNA extraction and sequencing—especially in  
136 the tropics that have one of the highest biodiversities of fish in the world (Lambrides  
137 and Weisler 2015). Furthermore, the majority of fishing communities occupy  
138 ‘exposed’ sites in coastal tropical and sub-tropical zones, with a consistently hot  
139 climate that fluctuates annually between dry and humid. These landscapes often lack  
140 natural and permanent shelter formations (such as caves), and are not typically  
141 conducive to aDNA preservation. Nevertheless, aDNA has been retrieved from  
142 tropical zones before (e.g., Gutiérrez-García *et al.* 2014, Murray *et al.* 2012, Nicholls  
143 *et al.* 2003, Schroeder *et al.* 2015), including Madagascar (Kistler *et al.* 2014,  
144 Mitchell *et al.* 2014, Orlando *et al.* 2008), and the innovation of new methods  
145 promises to increase the successful application of aDNA analysis on materials  
146 collected in tropical localities.

147

148 The recently developed ‘bulk-bone metabarcoding’ (BBM) approach is one such  
149 method that allows the DNA from many bones to be extracted, amplified, and  
150 sequenced in parallel to rapidly and accurately identify many of the taxa within a sub-

151 fossil assemblage (Grealy *et al.* 2015, 2016, Haouchar *et al.* 2014, Murray *et al.*  
152 2013), which can increase the probability of characterising tropical archeofish  
153 remains. Here, we demonstrate how the BBM method can retrieve molecular  
154 taxonomic information from Malagasy 100-300 ya archaeological fish bone fragments  
155 that can then be used to examine past interactions of humans with their marine  
156 environment.

157

## 158 **2 Materials and methods**

159

### 160 *2.1 Site description and dating*

161

162 The coastal ‘Andamoty-be’ archaeological site is located just north of the village of  
163 Andavadoaka (22° 04’S, 43° 14’E) in Toliara province, Southwest Madagascar  
164 (Figure 1a,b), and was excavated in June 2014 by K. Douglass. The site is bordered  
165 on the east by spiny forest and by the Mozambique Channel to the west. It is located  
166 within the Velondriake Marine Protected Area, a locally managed marine area  
167 (LMMA) that encompasses the longest continuous reef system in Madagascar and is  
168 protected under the International Union for Conservation of Nature (IUCN). A decade  
169 of reef and fisheries monitoring by Blue Ventures Conservation has generated an  
170 excellent modern record of marine biodiversity within Velondriake’s shallow reef  
171 flats, sand flats, macro-algae, sea-grass and mangrove habitats (Cripps 2009, Cripps  
172 *et al.* 2015, Hantanirina and Benbow 2013, Harris *et al.* 2010, Jones *et al.* 2014, Nadon  
173 *et al.* 2007, Roy *et al.* 2009). Human occupation at the site is estimated to date  
174 between 100 and 300 ya based on the presence of imported 19<sup>th</sup> century British  
175 stoneware ceramics and Venetian glass trade beads found in the accumulation. The  
176 site has been described in detail elsewhere (Douglass 2016).

177

178 Two replicate 2 m x 2 m units were placed on areas with the highest density of  
179 surface scatter approximately 20 m apart and 500 m from the shoreline. Layers were  
180 excavated following the natural stratigraphy, resulting in four layers per unit with  
181 multiple sub-contexts within layers (Figure 1d). Excavated material was sieved on-  
182 site using 2 mm x 2 mm mesh screens. Bones were subsequently sorted from cultural  
183 material and stored at room temperature. Gloves and facemasks were worn during  
184 excavation, sieving, and sorting to minimise contamination with modern DNA.  
185 Gloves did not come into contact with modern fish at any time during the excavation  
186 to ensure that no contamination by modern fish DNA was introduced to the samples  
187 during collection.

188

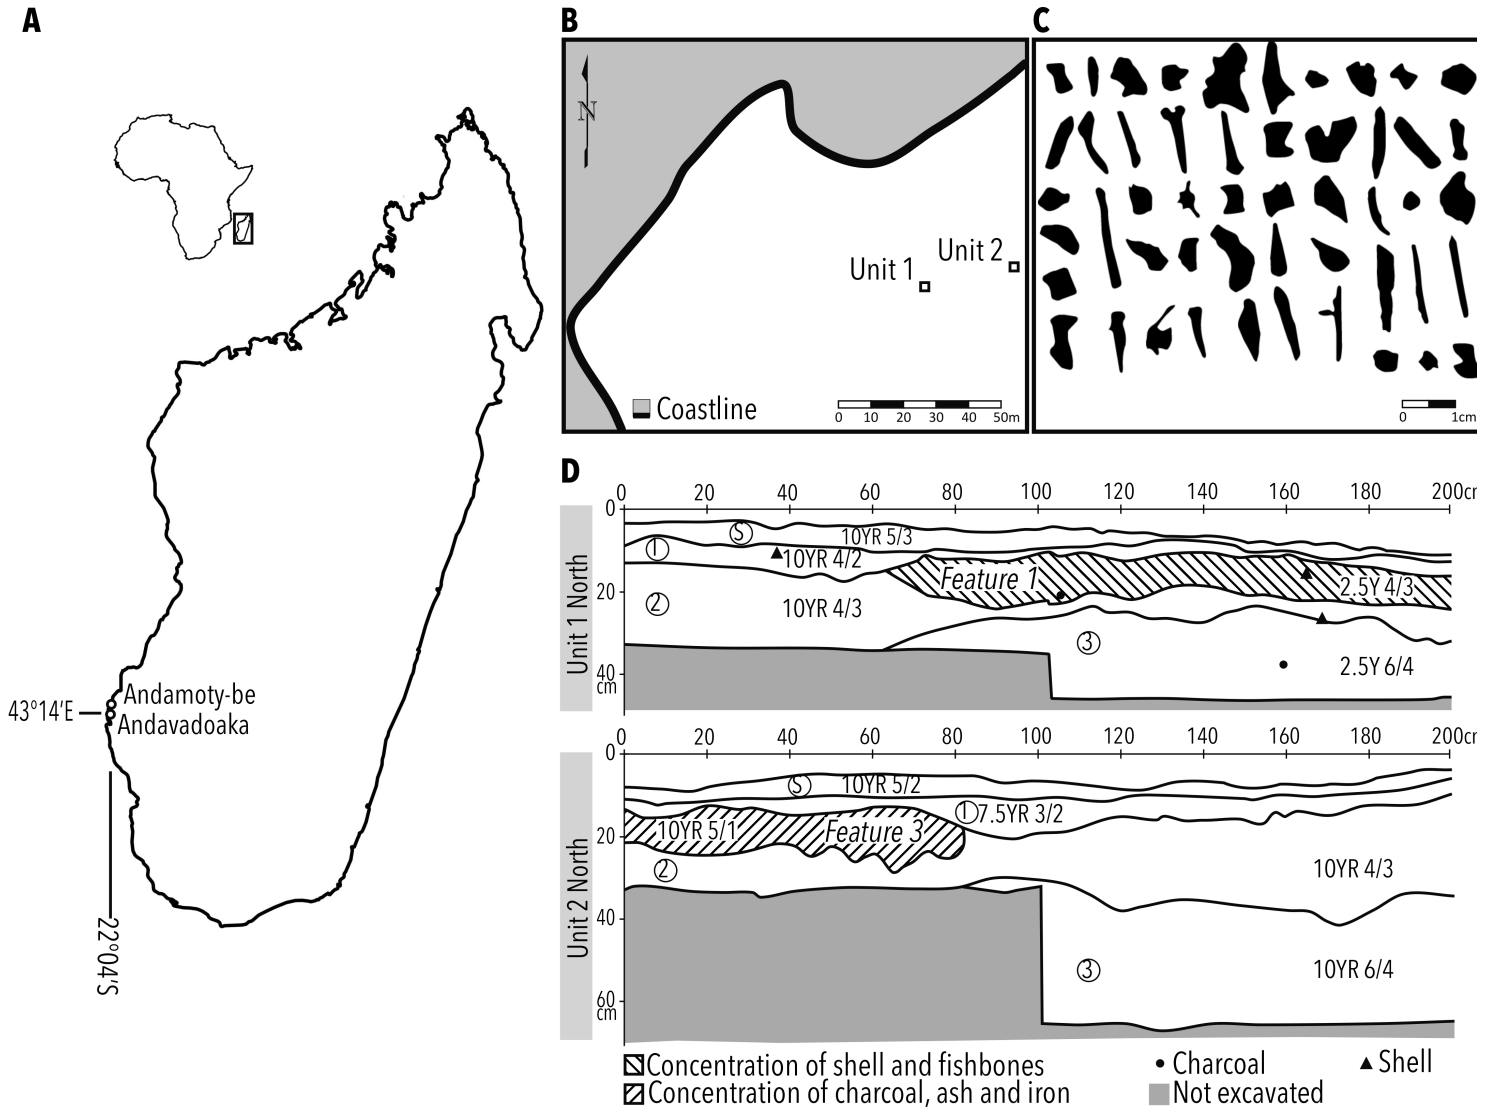

### 189 *2.2 Sample preparation*

190

191 Where possible, one pool of 50 bones (Figure 1c) was randomly generated for each  
192 context for a total of 13 pools (note that two contexts contained fewer than 50 bones;  
193 for these, all bones were pooled). Three additional pools of 50 bones were generated  
194 for the first layer in each unit (6 total) that targeted fish vertebrae fragments. A total  
195 of 887 bones were sampled, with each bone having an average mass of 123.5 mg.  
196 Approximately 20 mg of bone was subsampled from each bone within a pool and  
197 these were ground into a fine powder using the *Retsch* PM200 Planetary Ball Mill at  
198 500 rpm for 5 minutes. Powder was stored at -20°C. All sample preparation was  
199 conducted in an isolated ultra-clean environment within Curtin University’s TRACE

Bruwer; vertical axis represents depth). Note that these are examples of the stratigraphy and do not depict all contexts (for further detail refer to Douglass 2016).

246 facility (WA, Australia) following standard aDNA protocols for contamination  
247 avoidance (Willerslev and Cooper 2005; Knapp *et al.* 2012).

248

### 249 2.3 aDNA extraction

250

251 aDNA was extracted from 100 mg of bone powder for each pool, following the  
252 methods described by Grealy *et al.* (2016). DNA-free controls were included  
253 throughout the extraction processes and were carried through to sequencing.

254

### 255 2.4 Metabarcoding and next-generation sequencing

256

257 Primers targeting typical barcoding genes *COI* and *Cytb* tend to amplify regions that  
258 are too long to capture degraded DNA fragments of ancient samples (Jordan *et al.*  
259 2010). Therefore, aDNA extracts were amplified via qPCR using a primer set  
260 designed to target conserved regions of the fish 12S rRNA mitochondrial gene. At  
261 53°C, these primers (12S 5'-CGCCTATATACCRCCGTC-3' and 5'-  
262 CRCTACACCTCGACCTG-3', flanked by unique indexes and *Illumina* sequencing  
263 adapters) amplify a 56 bp variable barcoding region from local members within more  
264 than 60 fish families. *In silico* analysis of the primer-binding sites shows that they are  
265 conserved across modern taxa found in the area, and are not likely to be inherently  
266 more biased towards the detection of any one taxon over another (SI 1.0, Figure S1).  
267 In most cases, the metabarcoding region differs by five or more base pairs between  
268 taxa of interest (Table S1), and it is unlikely that the combined effect DNA damage,  
269 amplification error, and sequencing error would result in taxonomic mis-  
270 identifications (SI 1.0, Table S2). Amplification, subsequent sequencing on the MiSeq  
271 platform, trimming, and quality control were performed as per Grealy *et al.* (2016).  
272 DNA sequences are available on the online data repository Data Dryad and can be  
273 accessed via the doi:XXX\_XXX

274

### 275 2.5 Taxonomic assignment

276

277 Taxonomy was assigned to sequences by comparison with NCBI's GenBank (Benson  
278 *et al.* 2006) nucleotide reference database using BLASTn (default parameters;  
279 Altschul *et al.* 1990) implemented through the Pawsey Supercomputing Centre (WA,  
280 Australia), and examination in MetaGenome Analyser (MEGAN v. 4.70.4; Huson *et al.*  
281 2007) as per Grealy *et al.* (2016). Identifications were based on the similarity of  
282 query and reference sequence across 100% of the query, with similarity cut-offs for  
283 species-level IDs at >98% similarity, genus-level IDs at 95-98% similarity, and  
284 family-level IDs at 90-95% similarity. Assignments were assigned a credibility rating  
285 (highly credible, credible, or unlikely; Table 1) based on whether the taxa are found in  
286 area according to species' distribution records defined by FishBase (Froese and Pauly  
287 2015), and whether genetic reference sequences exist in GenBank for all subtaxa  
288 within family or genus.

### 299 3 Results and Discussion

300

301 Next-generation sequencing of 56 bp 12S rRNA sequences amplified from bulk fish bone  
302 aDNA generated a total of 77,298 reads (an average of 4024 reads per pool) and 1338 unique  
303 reads (an average of 70 unique reads per pool). After molecular taxonomic identification by  
304 comparison with a reference database, 23 families were identified with high credibility;  
305 within them, 14 genera were able to be identified with high credibility, 4 credibly, and within  
306 those, 5 species were able to be identified with high credibility and 6 credibly (Table 1). No  
307 fish DNA was amplified in any of the controls, indicating that contamination from the  
308 laboratory environment was below detectable levels.

309

310 Despite the large diversity of taxa identified, habitat associations derived from modern  
311 fisheries data (Blue Ventures) suggest a primary reliance on near-shore reef-dwelling fish,  
312 with 53% of identified families associating with coral reefs, and the remainder associating  
313 with seagrass (8%), mixed habitats (11%), or unknown (28%). These data suggest that there  
314 was a strong dependence on coral communities in terms of the exploitation of marine taxa. It  
315 appears that a range of fish sizes were targeted, and although not enough sampling has been  
316 done thus far to draw comparisons between layers, species within the family Lethrinidae  
317 (followed by Scaridae and Serranidae) were detected in more samples than any other taxa.  
318 This suggests that these typically large-bodied, high trophic-level fish may have constituted  
319 the primary staple marine food of people at Andamoty-be; in contrast, these families  
320 represent a small percentage of the catch in near-by Morombe today (Laroche *et al.* 1997).  
321 At Morombe, “high fishing pressure [has] led to a concentration of effort on lower trophic  
322 level species to maintain catch levels” (Laroche *et al.* 1997), an example of “fishing down  
323 marine food webs” (Pauly *et al.* 1998). This may indicate that fishing pressure in this region  
324 has increased over several hundred years, and that line fishing (the predominant method  
325 employed for catching high trophic-level fishes) may have been more commonly practiced  
326 by ancient communities than it is at present; today, only about 6% of catch in the Morombe  
327 region is by line (Laroche *et al.* 1997).

328

329 Other fish families detected include reef dwelling fish of the Chaetodontidae and  
330 Pomacentridae families (a mix of corallivores, planktivores, omnivores and herbivores, some  
331 of which are small and may have been used as bait fish), carnivores such as the wrasses of  
332 the Labridae family, members of the Carangidae family, and members of the Sparidae  
333 family. *Megalops cyrinoides* (Indo-Pacific tarpon) of the Megalopidae family are typically  
334 migratory fish that move between open water and inland rivers (Merrick and Schmida 1984).  
335 In the modern fisheries data (Blue Ventures), Megalopidae were recorded from catch in the  
336 coral habitat, suggesting that although adult fish could have been caught in the open sea  
337 beyond the barrier reef, they may have been netted, as adolescent *M. cyrinoides* migrate  
338 offshore from estuarine waters and mangroves (Coates 1987). Pelagic fish, like members of  
339 the Chanidae family (*Chanos chanos*, or milkfish), also possibly indicate open sea fishing;  
340 these fish live in large schools in surface waters over the continental shelf and generally  
341 require sophisticated fishing methods, including nets, larger outrigger canoes than are needed  
342 for fishing around coral reefs, and potentially the co-operation of several boats (Wheeler and  
343 Jones 1989). However, like members of the Megalopidae family, milkfish do migrate into  
344 brackish waters (including mangroves, estuaries, and lakes) as juveniles and return to the sea  
345 to sexually mature (Froese and Pauly 2015). Requiem sharks (*Carcharhinus*) are also known  
346 to occur in brackish and freshwater habitats. The presence of demersal fish such as the  
347 whitespotted whiplay (*Himantura gerrardi*) may indicate the practice of bottom trawling or  
348 line fishing. In addition to serving as a food source, stingrays are commonly sought out in

349 Velondriake today as a valuable source of abrasive material, and their tails are used as a tool  
350 to shape and sand wood (Douglass 2012).

351

352 Several taxa identified have not been recorded in modern fisheries data (Blue Ventures).  
353 These include carnivores such as *Psammoperca waigiensis* (Waigeo barramundi) of the  
354 Latidae family and Ginglymostomatidae (nurse sharks), fresh-water fishes of the Cichlidae  
355 family, and forage-fishes of the Clupeidae family. The detection of nocturnal predators such  
356 as nurse shark and Waigeo barramundi may be an indication of night fishing, dive fishing, or  
357 leaving nets out overnight. In particular, nurse sharks are bottom feeders that live in shallow  
358 inshore waters with coral communities. Overfishing may be responsible for the rarity of  
359 these sharks today (Cooke 1997), indicating that there has been significant anthropogenic  
360 impact on the environment by past people. Furthermore, the “season of abundance” for  
361 sharks is predominantly April to July (Langley 2006), which may indicate that this site was  
362 inhabited during the cooler, dry season.

363

364 Detection of the Cichlidae family is interesting as this is the only non-marine family  
365 identified in the archaeological assemblage thus far, and no cichlid catch is recorded in the  
366 modern fisheries data (Blue Ventures). Cichlids are a diverse family, with 28 endemic and 9  
367 introduced species known from Madagascar (Froese and Pauly 2015). This identification is  
368 strongly suggestive of fresh and/or brackish water fishing by local people. The closest  
369 occurrence of cichlid species to Andamoty-be is the Onilahy river basin’s *Ptychochromoides*  
370 *betsileanus* and *Ptychochromis onilahy*: these species are classified by the IUCN as critically  
371 endangered and extinct (respectively) as a result of habitat loss, fishing, and competition or  
372 predation by introduced species. The Onilahy River is located approximately 180 km south  
373 of Andamoty-be, so the presence of a cichlid at Andamoty-be could be an indication that the  
374 ranges of one or both of these species extended as far as Andamoty-be in the past, but  
375 underwent a range contraction as a result of human pressures. With more research, a historic  
376 range could potentially be established for these species, which may inform conservation  
377 efforts (Hofman *et al.* 2015, Speller *et al.* 2012). To confirm the identification of cichlids,  
378 additional samples and metabarcoding genes should be sequenced.

379

380 Finally, the detection of Clupeidae DNA (100% sequence similarity to *Sardina pilchardus*)  
381 in only the surface scatter layer is likely to have been derived from contamination by  
382 imported sardines: they are not native species but are a common component of human diet in  
383 Madagascar today. Although other sardine genera have been recorded in the modern  
384 fisheries data, these are generally well represented in genetic databases and their sequences  
385 differ from *Sardina pilchardus* by more than 9%, making it unlikely that this DNA  
386 originated from native sardine species.

387

388 Like osteological approaches, not all taxa can be identified to the species-level, and some  
389 taxa are likely to have not been detected at all (c.f., Grealy *et al.* 2015 for an in-depth  
390 discussion of the biases and limitations of the method where a direct comparison with a  
391 morphological approach was possible): Table 1 shows that some taxa are not consistently  
392 detected between replicates, highlighting that the ability to detect a given taxon in a complex  
393 mixture can be variable. Similar to other metabarcoding approaches such as bacterial  
394 metagenomics or environmental DNA monitoring, this ability to identify taxa genetically is  
395 influenced by: (1) the intensity of sampling, (2) unique taphonomic biases that affect DNA  
396 preservation (including pH, temperature fluctuations, and exposure to humidity), (3)  
397 collection and storage (such as handling that can introduce contamination), (4) choice of  
398 barcoding region (high intraspecific variation at a locus can affect taxonomic resolution), (5)

399 incomplete reference genetic databases (while comprehensive, some taxa may not be  
400 represented), and (6) DNA damage, PCR bias, and sequencing error (although these can  
401 largely be mitigated by adequate sequencing depth, PCR replication, diluting inhibitors, and  
402 stringent quality control). Nevertheless, the detection of one taxon is not undermined by an  
403 inability to detect another, although we cannot confidently estimate what we did *not* find. In  
404 addition, although the amplification of longer fragments may have resulted in more refined  
405 taxonomic identifications, the degradation of aDNA in tropical environments typically  
406 results in the majority of fragments being very short; as such, there is a trade-off between the  
407 breadth of taxa identified and the specificity of identification (Greal *et al.* 2015). Analysis  
408 of more samples, amplification of additional barcoding genes, and revisiting the existing data  
409 as genetic databases become more complete, will also deliver more fine-scaled molecular  
410 identifications and identify additional diversity. While not a complete audit of the past fish  
411 diversity, this is the first published description of an archaeological fish assemblage from  
412 southwest Madagascar, and demonstrates that a genetic approach provides useful  
413 zooarchaeological information in the absence of an alternative. The analysis of additional  
414 DNA extracts in the future will allow us to potentially compare archaeofish biodiversity  
415 between Andamoty-be and other archaeological sites in Madagascar.

416

#### 417 **4 Conclusions**

418

419 This study has established the first published marine zooarchaeological record for  
420 Velondriake, offering insights into how past coastal communities derived a livelihood from  
421 local marine resources. This is particularly important to establish as accelerated rates of  
422 environmental degradation, resource over-exploitation and loss of faunal diversity in recent  
423 times have generated important concerns about the future of Madagascar's natural  
424 communities and the ability of human communities to derive sustainable livelihoods,  
425 especially in a region where more than a third of the population currently engage in sea  
426 fishing (Laroche *et al.* 1997). The data presented here provide a baseline upon which future  
427 data collection and analysis may build, and knowledge of historic biodiversity and human  
428 exploitation of the marine environment may assist in conservation and management  
429 decisions. *Post-hoc* comparisons with morphological analysis of fossil assemblages in  
430 Velondriake will confirm the accuracy (or otherwise) of the molecular identifications.  
431 Nevertheless, this study suggests that other archaeological sites around Madagascar, and in  
432 other tropical regions, may benefit from aDNA analysis of bulk bone to expand the  
433 taxonomic identifications obtained through traditional methods, and hopefully will  
434 encourage more fruitful collaborations between geneticists and archaeologists.

435

#### 436 **5 Acknowledgements**

437

438 The archaeological investigations carried out in the Velondriake Marine Protected Area,  
439 were made possible with funding from the National Science Foundation Graduate Research  
440 Fellowship Program, the P.E.O. Scholar Award, the Yale Institute of Biospheric Studies, the  
441 Yale MacMillan Center for International and Area Studies and the Yale Council on  
442 Archaeological Studies. Research permissions were granted by the Ministère de  
443 l'Enseignement Supérieur et de la Recherche Scientifique, Autorisation Numéro 128/13-  
444 MESupReS/SG/DGRP and by the Centre de Documentation et de Recherche sur l'Art et les  
445 Traditions Orales Malgaches (CEDRATOM), under the auspices of the Memorandum of  
446 Understanding between the University of Toliara, under the direction of Dr. Barthélémy  
447 Manjakahery, Director of the CEDRATOM, and Yale University, under the direction of Dr.  
448 Roderick McIntosh, Professor of Anthropology. Local permission to carry out archaeological

449 research was granted by the Office du Maire, Commune de Befandefa and by the Chefs de  
450 Fokontany of Andavadoaka, Nosy Ve, Antsaragnangy, Lamboara, Ampasilava and  
451 Salary. Permits for the export of archaeological materials for the purposes of laboratory  
452 analysis were granted by the Secretariat Général of the Ministère de l'Artisanat de la Culture  
453 et des Patrimoines, Direction Régionale de la Culture et du Patrimoine Atsimo Andrefana,  
454 Visas de Sorties Numéro 09/06-MCP/SG/DRCP.AA; Numéro 05/14-MACP/SG/DRCP.AA;  
455 Numéro 08/14-MACP/SG/DRCP.AA in accordance with Avis Numéro 375, 02/02/1978. We  
456 acknowledge the support of the Australian Research Council Discovery Project grant  
457 DP160104473 (MB).

458

459 We give special thanks to the Morombe Archaeological Project (MAP) team, to the people  
460 of Andavadoake, Madagascar, and to Blue Ventures conservation for sharing data pertaining  
461 to modern Velondriake Fisheries. We would also like to thank James Taylor for his  
462 assistance with sample preparation and sequencing, and Joey DiBattista for offering insights  
463 into fish behavior. High-throughput BLAST searches were performed through the Pawsey  
464 Supercomputing Centre (Perth).

465

## 466 **6 Author contributions**

467

468 KD organised and directed the archaeological excavation. AG and JH assisted with the  
469 collection of bulk bone material. AG conducted genetic analyses with assistance from MB.  
470 JH designed the primers used. CG provided modern fisheries data for comparison. CB  
471 rendered the line drawings and figure. AG and KD drafted the manuscript with contributions  
472 and edits from all co-authors.
