Abstract

Computed tomography (CT) is currently a widely available imaging technique in clinical practice. Technical developments of CT imaging, especially the emergence of multislice CT, with increased scanning speed and volume, higher spatial and temporal resolution, have significantly enhanced the diagnostic value of CT in many clinical applications. CT has become an important diagnostic imaging modality in the emergency department, with high diagnostic accuracy and efficacy in both traumatic and non-traumatic conditions. There is however a growing concern about the risk of associated radiation exposure in the population exposed to CT examination. Justification of the application of CT is one of the main principles that physicians need to be aware of when choosing CT as the first line technique for diagnosis. This article reviews the clinical applications of CT imaging in the emergency department, with focus on patients presenting with headache, repeat and multiple CT imaging and whole body screening for trauma patients, and explore whether the applications are clinically justified.

Keywords: computed tomography (CT), emergency department, trauma, radiation dose, radiation risk
Introduction
Since its first introduction into clinical practice in the early 1970s, the use of computed tomography (CT) has been progressively growing worldwide. According to the 2006 report (1) of the United Nations Scientific Committee on the Effects of Atomic Radiation, the frequency of CT examinations in developed countries increased on average from 6.1 per year per 1,000 population in the 1970s to 48 per year per 1,000 population in the period between 1991 to 1996 (2). At the same time, the average effective dose per CT examination increased from 1.3 mSv (millisieverts) in the 1970s to 8.8 mSv in the period between 1991 to 1996 (2). During the last two decades, CT has undergone rapid technical developments which include the introduction of helical CT and multislice CT scanners which decrease or eliminate motion artifacts, acquire volumetric data in a short time with great anatomic coverage, and generate isotropic datasets which facilitate 3D reconstruction of anatomical areas (3, 4). These advantages have led to a rapid increase of CT utilisation in both adults and children (5-8). The estimated annual number of CT examinations in the United States rose steadily from 2.8 million in 1981 to 20 million in 1995 (7), 46 million in 2000 (8) and more than 62 million CT scans in 2006 including 4 million for children (9). Comparable trends have been reported in European countries such as Germany, Switzerland, Norway and UK (10). All these data indicate that CT has become the method of choice in many clinical applications in both daily practice and emergency department.

It is estimated that CT accounts for 10% of all diagnostic radiologic examinations but it contributes up to 70% of the collective radiation dose delivered to patients (11). The growing use of CT comes with growing concern about risks associated with diagnostic CT. The risk is estimated by looking at the expected number of cancers in a specific population and the actual numbers observed in the exposed cohort (12). The National Academy of Science report on the Biological Effects of Ionizing Radiation (BIER VII) estimated that a single population dose of 10 mSv is associated with a lifetime risk for developing a solid cancer or leukaemia by 1 in 1000 exposures (13). The small potential risk of cancer associated with CT must be considered in the context of the potential survival benefit from undergoing CT examination. Tables I and II show the radiation
dose of CT examination in various anatomic regions in comparison to the radiation dose resulting from corresponding conventional radiography (14). As McCollough et al claimed (12), the life risk of a fatal cancer from all causes is 22.8%, and the lifetime potential risk of a fatal cancer from the radiation associated with a body CT scan is approximately 0.05%. Thus, the benefit-to-risk ratio for any patient will be driven by the benefit and appropriateness of the CT examination. The three fundamental principles of radiation protection in radiology are justification of utilisation, optimisation of protection and limitation of dose limits (15). Optimisation and limitation have been studied widely in the literature, while the first principle, justification is still controversial in many areas with regard to the judicious use of CT. Although difficult to fully assess, it has been reported that 30% or more of the CT scans currently performed may be unnecessary (16). Substantial increases of CT utilisation were noted over the last decade in the emergency department which ranged from an increase of 51% to 463%, depending on the anatomic regions imaged (17-19). In the following sections, we will discuss the applications of CT in the emergency department with respect to the patients presenting with headache, repeat and multiple CT scan, and whole body screening in trauma patients.

**Application of CT in patients with headache**

Headache accounts for a large number of emergency department visits (20). CT imaging remains the initial imaging investigation of choice for new-onset headache in adults and headache suggestive of subarachnoid haemorrhage (21). Because pathology presenting solely with headache is uncommon, a large proportion of the imaging studies will have negative findings (22, 23). Guidelines have been developed for imaging headache by the United States Headache Consortium, the American College of Emergency Physicians, and the American College of Radiology Expert Panel on Neuroimaging (24). The general recommendations are that screening patients with isolated headache by CT or magnetic resonance (MR) imaging is usually not warranted.

Previous studies have shown that CT and MR imaging are of very low diagnostic value when applied as screening tools in patients imaged for isolated nonfocal headaches (22, 23). Jordan et al (25) recently reported that CT imaging of nonfocal headache in
emergency setting had limited cost efficacy due to lower percentage of positive clinically significant results. 31.8% positive CT findings were found in their study group, but only 1.02% showed clinically-significant results which required a change in patient management. Similarly, a chief complaint of trauma headache predicted a normal or clinically insignificant CT angiography according to a recent report (26). In contrast, an abnormal head CT is a strong predictor of clinically significant CT angiography. Jamshidi et al (26) found that 54% of patients had an abnormal non-contrast head CT, and 41% of all CT angiography were abnormal. Since CT imaging of emergency headache has become a widespread and growing problem with significant economic implications, the physicians need to follow guidelines and justify the use of CT in patients presenting with headache in the emergency department (25). Table III summarises the indications of recommending head CT scans in the emergency department.

**Application of CT in patients with repeat or multiple CT scans**

Increased use of CT has resulted in growing rates of repeat or multiple imaging in various patient populations presenting with different clinical scenarios. This has emphasised the concerns about appropriateness, cost control, resource utilisation in both emergency and non-emergency situations. A recent American College of Radiology white paper (2007) on radiation dose in medicine provides many innovative suggestions for controlling radiation exposure, including development of “a surveillance mechanism to identify patients with high cumulative radiation doses due to repeated imaging” (18). However, data are still limited regarding patients undergoing frequent imaging and the associated radiation risks, as well as subsequent potential risks of developing fatal malignancy.

Wiest et al (27) reported that 30% of all patients undergoing CT had more than three CT studies in their film records, 7% had more than five, and 4% had more than nine. Broder et al (17) found that 79% of patients evaluated in the emergency department for renal colic underwent two or more CT scans, 30% of which had more than three CT scans, and 10% had five or more CT scans. Jaffe et al (28) found that 9% of patients followed at their institution for Crohn’s disease underwent more than five abdomen or pelvis CT
examinations and 3% more than 10 examinations, with effective dose ranging from 39.9 to 133 mSv. Griffey and Sodickson (29) looked at the patients visiting the emergency department at least three times per year undergoing multiple imaging tests. They noticed that over a 7.7-year period, 130 patients underwent 1744 CT studies, of which 55% were performed in the emergency department. More than half of the patients in their cohort underwent 10 or more CT studies and accumulated more than 91 mSv of cumulative radiation dose, with an estimated lifetime risk of developing a radiation-induced cancer of one in 100 or greater (29).

This raises the risk-to-benefit equation that clinicians need to face in the emergency department with regard to the decision as to whether to image the patient again with CT or recommend another imaging technique to reduce the radiation risk associated with multiple CT scans. Approaches to reduce cumulative radiation risks to these patients include dose reduction of each CT examination (such as automated tube current modulation, imaging parameter selection or protocol modifications) and utilisation of standardised reference dose levels. A risk-benefit decision must be made at the level of the individual patient and should involve balancing the highly context-dependent benefits of CT imaging against the patient-specific cumulative risks (30).

**Application of CT for whole body screening in trauma patients**

Rapid imaging, more accurate and more accessible CT scans have changed the indications from being symptom driven to nonsymptom or mechanism driven (31). CT along with 3D reconstruction visualisations has proven to be valuable in detecting and characterising injuries associated with trauma patients (32, 33). Several reports recommended the use of CT as both a screening and diagnostic tool, and some suggested that CT could replace the use of radiography in certain traumatic situations (34, 35).

Performing whole body imaging on unevaluable patients has become an accepted protocol in many trauma centers (36, 37). The fear of missing an injury in a patient who cannot be reliably examined has made whole body scanning these patients routine when compared to diagnostic peritoneal lavage (36). Even if in evaluable patients, liberal CT
scanning is advocated due to the unreliability of physical examination (38, 39). Mackerise et al (40) found only a 65% diagnostic accuracy for physical examination alone in evaluating abdominal injury. Self et al also reported similar imprecision in that 38% of the patients with negative physical examinations had positive CT findings (35). Some would argue that a CT scan has replaced physical examination in trauma patients. Clinical studies supported the use of CT in whole body imaging in trauma patients in the emergency settings (36-41).

Previous studies reported that CT is performed in up to 67% of patients presenting to emergency departments (40, 41). Currently, many centres are equipped with dedicated CT scanners to allow fast access for trauma patients and various medical emergencies (42, 43). The recent introduction of multislice CT (16 and 64-slice) in the emergency department has changed CT from a conventional transaxial sectional imaging to a 3D isotropic imaging technique (44, 45). The huge improvement in CT performance reduces scanning time and section collimation, therefore this favours multislice CT for imaging trauma patients. In addition to the diagnostic value of CT in imaging patients presenting with traumatic injury to the individual organs (34, 35, 37, 46), the CT technique has been reported to be a valuable modality for whole body imaging in terms of better patient management and diagnostic accuracy (47-50).

Self et al (36) reported that 38% of 457 patients who underwent head, thorax, abdominal and pelvic CT scans in blunt multitrauma had unexpected findings that were not detected by conventional radiographic examinations. Changes of treatment plan were made in 26% of the study group because of the results found on the CT scans, while in the meantime additional whole body CT scans added minimal costs to the care of trauma patients. Salim et al (47) found that 19% of 1000 patients without obvious external signs of injuries resulted in a change of treatment based on the results of whole-body CT scan. This is also supported by a recent report published in the Lancet (50). Huber-Wagner et al in their multicentre study, found that whole-body CT is an independent predictor of survival for patients with major trauma. They recommended the whole-body CT as a standard diagnostic method during the early resuscitation phase for multitrauma patients.
In addition to the diagnostic value, whole body CT (a single pass continuous CT scan) was found to result in lower radiation dose than do conventional segmented acquisitions with scanning of body segments individually (50-52). Ptak et al (52) reported a 17% reduction in radiation dose when a single-pass examination was used when compared with the dose administered in the conventional segmented protocol. The estimated lifetime risk of cancer from a single whole-body CT examination is about 1 in 1250 for a 45-year-old adult and 1 in 1700 for a 65-year-old adult (53). However, the estimated risks for multiple CT examinations are correspondingly higher with potentially accumulated estimated life-time cancer risk of up to 1.9% (about one in 50) (53).

**Summary and conclusion**

There is no doubt that CT has become the most valuable diagnostic modality in the emergency department. Rapid technical developments in CT imaging and the increased availability reflect the significant increase of CT utilisation in the adult emergency department. The increased use of CT also represents a potentially large radiation exposure for patients. Physicians need to be aware of this potential risk associated with CT imaging. The increase of CT utilisation in emergency department should ultimately be justified by improving healthcare outcomes. The benefit-to-risk ratio for imaging patients in emergency department must be driven by the benefit and appropriateness of the CT examination requested by the physicians. The main purpose of utilising CT imaging is to address specific clinical question without allowing concerns about radiation exposure to dissuade physicians or their patients from obtaining or undergoing the needed CT examination. This review has highlighted that CT has been advocated in the diagnosis and management of trauma patients, however, for patients with headache and repeat or multiple CT scans in the emergency department, use of CT must be justified with regard to the potential risk of radiation exposure.

</tbody>
</table>
| Emergent CT imaging is recommended to determine if it is safe to do lumbar puncture | • Headache accompanied by signs of increased intracranial pressure  
• Headache accompanied by fever and neck stiffness and meningeal signs |
| Emergent CT imaging should be considered (under the category of new onset headache, CT is the first line technique, followed by CT angiography or MR imaging to confirm diagnosis) | • Isolated “thunderclap” headache  
• Headache radiating to neck  
• Temporal headache in an older individual (after age 50)  
• New onset headache in patient who is  
  o HIV positive  
  o has a prior diagnosis of cancer  
  o is in a population at high risk for intracranial disease  
• Headache accompanied by abnormal neurological examination, including papilledema or unilateral loss of sensation, weakness, or hyperflexia |
| Emergent CT imaging is not usually warranted | • Migraine and normal neurological exam |
| Emergent CT imaging is not recommended (Some evidence for increased risk of intracranial abnormality, not sufficient for recommendation) | • Headache worsened by Vasalva maneuver, wakes patient from sleep, or is progressively worsening |
| Emergent CT imaging is not recommended (insufficient data) | • Tension type headache and normal neurological exam |
