## Abstract

We present observations of the first ten degrees of longitude in the Mopra carbon monoxide (CO) survey of the southern Galactic plane (Burton et al. 2013), covering Galactic longitude  $l = 320\text{--}330^\circ$  and latitude  $b = \pm 0.5^\circ$ , and  $l = 327\text{--}330^\circ$ ,  $b = +0.5\text{--}1.0^\circ$ . These data have been taken at 35 arcsec spatial resolution and  $0.1\text{ km s}^{-1}$  spectral resolution, providing an unprecedented view of the molecular clouds and gas of the southern Galactic plane in the 109–115 GHz  $J = 1\text{--}0$  transitions of  $^{12}\text{CO}$ ,  $^{13}\text{CO}$ ,  $\text{C}^{18}\text{O}$  and  $\text{C}^{17}\text{O}$ . Together with information about the noise statistics from the Mopra telescope, these data can be retrieved from the Mopra CO website and the CSIRO-ATNF data archive.

**Keywords:** Galaxy: kinematics and dynamics – Galaxy: structure – ISM: clouds – ISM: molecules – radio lines: ISM – surveys

## 1 INTRODUCTION

Molecular clouds comprise the densest regions of the interstellar medium, and are the nurseries in which stars form. In order to determine how molecular clouds themselves form, surveys of the three principal forms of carbon (i.e.  $\text{C}^+$ ,  $\text{C}$  and  $\text{CO}$ ) are needed to trace the gas in its ionised, atomic and molecular forms respectively. In particular, surveys along the Galactic plane, where the great majority of molecular clouds lie, provide us with a picture of the molecular structure of our Galaxy.

The Mopra southern Galactic plane CO Survey is designed to map the distribution and dynamics of the carbon monoxide (CO) molecule along the Fourth Quadrant of the Galaxy, from  $l = 270\text{--}360^\circ$  with  $b = \pm 0.5^\circ$  (Burton et al. 2013, Paper I). Using the Mopra radio telescope, the  $J = 1\text{--}0$  line of CO at 2.6 mm is being mapped at 35 arcsec spatial and  $0.1\text{ km s}^{-1}$  spectral resolution, in order to determine where giant molecular clouds (GMCs) lie in the Galaxy and to explore

the connection between molecular clouds and the ‘missing’ gas inferred from gamma-ray observations. The CO data will be combined with similar survey data collected of the sub-millimetre neutral carbon line (C) taken with the Nanten2 telescope in Chile, and the terahertz neutral and ionized carbon lines (C and  $\text{C}^+$ ) from the balloon-borne Stratospheric Terahertz Observatory 2 (STO2) and the ice-bound High Elevation Antarctic Telescope (HEAT), both in Antarctica. With these surveys it will be possible to determine the distribution and motion of the principal forms of carbon in the interstellar medium.

Data Release 1 (hereafter DR1) covers the first ten square degrees of the survey, from  $l = 320\text{--}330^\circ$  with  $b = \pm 0.5^\circ$ , along with an additional three half-square degrees over  $l = 327\text{--}330^\circ$ ,  $b = +0.5\text{--}1.0^\circ$  (see Figures 1 & 2). The G323 sightline has previously been published in Paper I, however, it is discussed here because the G323 data was taken in the summer months and compares less favourably to the other data cubes, which

**Figure 1.** Three-colour image of the Galactic plane from the Spitzer GLIMPSE 8  $\mu\text{m}$  (red; Churchwell et al. 2009; Benjamin et al. 2003) and MIPS GAL 24  $\mu\text{m}$  (green; Carey et al. 2009) surveys, with a moment 0 map calculated over  $v = -120$  to  $0 \text{ km s}^{-1}$  from the Mopra  $^{12}\text{CO } J = 1-0$  survey (blue). The region enclosed by the white box, containing Galactic longitudes  $l = 320-330^\circ$  and latitudes  $b = \pm 0.5^\circ$ , as well as  $l = 327-330^\circ$ ,  $b = +0.5-1.0^\circ$ , is that published here as Data Release 1 (DR1).

**Figure 2.** The moment 0 map calculated over  $v = -120$  to  $0 \text{ km s}^{-1}$  from the Mopra  $^{12}\text{CO } J = 1-0$  Southern Galactic Plane survey. The region illustrated is that published here as Data Release 1 (DR1).

were obtained in the Austral winter. The improved atmospheric conditions make it possible to observe all four of the major CO isotopologues ( $^{12}\text{CO}$ ,  $^{13}\text{CO}$ ,  $\text{C}^{18}\text{O}$  and  $\text{C}^{17}\text{O}$ ), although the  $\text{C}^{17}\text{O}$  line is very weak and only detectable at a  $2\sigma$  level at best, as measuring it typically requires longer integration times than our fast-mapping survey mode allows (see Paper I). The isotopologue ratios allow examination of the distribution of columns of molecular gas through GMCs (Heyer et al. 2009), so that variance in the  $X_{\text{CO}}$  factor, used to link the CO intensity to the  $\text{H}_2$  column density in order to obtain molecular cloud masses, can be determined (see e.g. Bolatto, Wolfire & Leroy 2013).

In Section 2 of this paper (Paper II) the data are described, along with the various metrics used to quantify the noise and data quality. Section 3 will present some sample science results, however detailed science investigations are left for focussed studies, such as Burton et al. (2014), which described a filamentary molecular cloud in the G328 sightline. The data are being made available at the survey website<sup>1</sup>, and in the CSIRO-ATNF data archive<sup>2</sup>, as they are published.

## 2 DATA RELEASE 1

The data presented in this paper were taken in March 2011, and over the Austral winters of 2011–2013. The observations performed in 2011 ( $l = 323-330^\circ$ ,  $b = \pm 0.5^\circ$ ) used the UNSW Digital Filter Bank (the UNSW-MOPS) in its ‘zoom’ mode, with  $4 \times 137.5 \text{ MHz}$  dual-polarization bands; in 2012 this was increased to 8 bands, so that the data from  $l = 320-323^\circ$ ,  $b = \pm 0.5^\circ$  and  $l = 327-330^\circ$ ,  $b = +0.5-1.0^\circ$  cover a larger spectral region. Very little emission is observed in these extended bands away from the Galactic centre, but it is possible that high velocity clouds could be detected. The full line parameters are given in Table 1 of Paper I; the DR1 dataset has a spectral resolution of  $\sim 0.1 \text{ km s}^{-1}$  over at least 4096 channels for each of the four CO isotopologues.

The angular resolution of the Mopra beam at 115 GHz is 33 arcsec FWHM (Ladd et al. 2005); after the median filter convolution is applied during the data reduction process, the beam size is around 35 arcsec in the final data set. The extended beam efficiency, used to convert brightness temperatures into line fluxes, is  $\eta_{\text{XB}} = 0.55$  at 115 GHz (rather than the main beam efficiency  $\eta_{\text{MB}} = 0.42$ ; Ladd et al. 2005).

There are a number of metrics used to assess the quality of DR1. Figure 3 shows histograms of the noise per

**Figure 4.** Maps showing the noise level (in  $T_A^*$  [K] units) for  $^{12}\text{CO}$  and  $^{13}\text{CO}$ , determined from the standard deviation of the continuum channels between 0 and  $+90\text{ km s}^{-1}$  for each pixel. Note that the intensity scales differ, as the  $^{12}\text{CO}$  observations have  $\sim 3\times$  higher noise than  $^{13}\text{CO}$ . The higher noise in the G323 region (Paper I) is also evident.

**Figure 3.** Probability distribution of the noise level in the  $^{12}\text{CO}$  (left) and  $^{13}\text{CO}$  data cubes,  $\sigma_{\text{cont}}$ , as determined from the standard deviation in the continuum channels (in  $T_A^*$  [K] units) for each pixel. The dotted distribution in each is the noise level in the  $l = 323\text{--}324^\circ$  field (described in Paper I), highlighting the effect of observing in the summer months.

channel,  $\sigma_{\text{cont}}$ , as well as the previously-published distribution from the G323 sightline for both the  $^{12}\text{CO}$  and  $^{13}\text{CO}$  lines (the  $\text{C}^{18}\text{O}$  and  $\text{C}^{17}\text{O}$  lines have similar noise characteristics to  $^{13}\text{CO}$ ). These are calculated by finding the standard deviation of the channels outside of the range where line emission occurs, where  $V_{\text{LSR}} < -120\text{ km s}^{-1}$  and  $V_{\text{LSR}} > +20\text{ km s}^{-1}$  (Figure 11 shows that some emission exists where  $V_{\text{LSR}} > +20\text{ km s}^{-1}$ , but it occurs in very few pixels and does not affect these statistics). Although the G323 data were taken in the summer months, the noise distribution is not significantly different from those data obtained in winter. While the tails of the histograms are  $\sim 0.5\text{ K}$  higher in the summer observations due to the poorer conditions,

the mode values for  $^{12}\text{CO}$  and  $^{13}\text{CO}$  are 1.5 and 0.7 K per  $0.1\text{ km s}^{-1}$  velocity channel, in comparison to 1.3 and 0.5 K per  $0.1\text{ km s}^{-1}$  channel in winter. The  $^{12}\text{CO}$  line has higher noise than the  $^{13}\text{CO}$  line (and those of the other isotopologues not shown here), as there is a molecular oxygen absorption line near 115 GHz, making the atmosphere inherently worse than it is for the other isotopologues at 109–112 GHz.

Figure 4 shows the  $1\sigma$  noise maps for the  $^{12}\text{CO}$  and  $^{13}\text{CO}$  data cubes, determined from the standard deviation of the continuum channels between  $v = 0$  and  $v = +90\text{ km s}^{-1}$  in each pixel. The wider visible striping in these maps is an effect of the scans in the  $l$  and  $b$  directions being taken with a variety of different system temperatures and observing conditions. Thinner stripes or spots of lower apparent noise occur where ‘bad’ pixels, rows or columns were identified and interpolated over (the lower noise is a result of interpolating over several nearby pixels; see Paper I). As in Figure 3, the higher noise occurring in the G323 field is a result of poorer conditions in the summer months.

The system temperature,  $T_{\text{sys}}$ , measures the level of the received signal from the source, sky, telescope and instrument. It is calibrated every 30 minutes with reference to an ambient temperature paddle that is placed in front of the beam. Figure 5 shows histograms of the probability distribution of  $T_{\text{sys}}$  for  $^{12}\text{CO}$  and  $^{13}\text{CO}$ , alongside their counterparts for the G323 sightline. Again, the  $^{12}\text{CO}$  line has  $T_{\text{sys}}$  about a factor of two higher than the values for the other lines due to the inferior conditions. Maps of the system temperature for all four of the CO isotopologues are shown in

**Figure 6.**  $T_{\text{sys}}$  images for (from top):  $^{12}\text{CO}$ ,  $^{13}\text{CO}$  and  $\text{C}^{18}\text{O}$  (which share the same 2 GHz band of the correlator), and  $\text{C}^{17}\text{O}$ , in units of  $T_A^*$  (K) (as indicated by the scale bars). The striping pattern is inherent to the data set, resulting from scanning in the  $l$  and  $b$  directions in variable observing conditions. The darkest square degree region,  $l = 323\text{--}324^\circ$ , was observed in March 2011 when the summer conditions were less favourable for CO observations.

**Figure 5.** Probability distribution of the system temperature,  $T_{\text{sys}}$  (in  $T_A^*$  [K] units) for  $^{12}\text{CO}$  and  $^{13}\text{CO}$ , in the data for each pixel, determined from the ambient temperature load paddle measurements. The dotted distribution in each is the  $l = 323\text{--}324^\circ$  field described in Paper I; the higher  $T_{\text{sys}}$  values highlight the effect of observing in the summer months.

Figure 6;  $^{13}\text{CO}$  and  $\text{C}^{18}\text{O}$  share the same  $T_{\text{sys}}$  map as these lines are in the same 2 GHz band of the correlator. As before, the striping is a result of combining data from scans in both the  $l$  and  $b$  directions (minimizing artefacts from poor sky conditions), while spots occur where the data cube has been thresholded to remove

that data with excessive  $T_{\text{sys}}$  values (see Paper I for more details). Scans with particularly high  $T_{\text{sys}}$  values were repeated (these are also visible in Figure 4 as wide stripes of lower noise).

Several of the data cubes were affected by contamination from faint molecular clouds in the sky reference beam (of typical intensity  $\sim -0.5$  K in  $^{12}\text{CO}$  and  $\sim -0.1$  K in  $^{13}\text{CO}$ ; the other lines are generally too weak for sky emission to be visible). While tests of the sky reference positions were carried out prior to survey observations, these were quick observations and the faint sky signal was typically lost in the noise. In DR1 this contamination has been removed by calculating the average spectra in a region of  $\sim 100$  pixels where the sky contamination is uniform, such that there is no true emission within  $\pm 3 \text{ km s}^{-1}$  of the negative emission profile. A Gaussian template is fit to this contaminating profile and then subtracted from the individual spectrum at each pixel in the full square degree. The central velocity of the sky emission varies across each square degree, as the reduction process (see Paper I) does not control for any variation relative to the local standard of rest in the sky spectrum; this is compensated for by linearly varying the central velocity of the template spectrum in

**Table 1** Sky reference beam positions for each square degree of DR1; the additional half-square degree regions from  $l = 327\text{--}330^\circ$ ,  $b = +0.5\text{--}1.0^\circ$  use the same sky reference positions as their main survey counterparts. Several of the cubes were affected by contamination due to  $^{12}\text{CO}$  line emission at the sky reference position; the central velocity and intensity (in  $T_A^*$  [K] units) of this contamination is also noted.

Cube	Reference Longitude	Reference Latitude	Contamination Velocity ( $\text{km s}^{-1}$ )	Contamination Peak Intensity ( $T_A^*$ [K])
G320	320.375	-3.000		
G321	321.500	-2.500	-1.68	-3.18
G322	322.500	-2.000	-56.11, -12.96	-1.25, -0.39
G323	323.500	-2.000		
G324	324.500	-2.000	+0.90	-0.78
G325	325.500	-2.200	-46.62	-0.49
G326	326.500	-2.000	-19.31	-0.55
G327	327.500	-2.200		
G328	328.500	-2.200	+2.68	-0.42
G329	329.500	-2.200		

both longitude and latitude (typically by  $\lesssim 1 \text{ km s}^{-1}$  in either direction). Table 1 gives the position of the sky reference beam for each square degree, along with the intensity and central velocity of the contamination in the average spectrum for the square degree.

DR1 has been made available at the survey website and in the CSIRO-ATNF data archive as a series of fits files for each isotopologue, each containing a square degree of the survey, centred at each half degree along the Galactic plane. Although the full range of velocity space available for  $^{12}\text{CO}$  is  $[-1000, +1000] \text{ km s}^{-1}$  (with file sizes  $\sim 800 \text{ MB}$  / square degree), it is expected that most users would prefer to download the smaller ( $\sim 300 \text{ MB}$  / square degree) files covering the velocity range  $[-150, +50] \text{ km s}^{-1}$  illustrated in this paper. No emission has yet been detected outside this range, although closer to the Galactic centre a wider velocity range will be included within the smaller files. Also available are the  $T_{\text{sys}}$ , beam coverage and rms noise images for each line. The  $10^\circ \times 1.5^\circ$  cube used for the analysis in this paper was created using the `imcomb` task in `miriad`<sup>3</sup> (Sault, Teuben & Wright 1995).

### 3 RESULTS

Figures 7 and 8 show the average  $^{12}\text{CO}$  and  $^{13}\text{CO}$  line profiles for each square degree cube in DR1. The  $^{12}\text{CO}$  profiles from the lower spatial ( $8'$ ) and spectral ( $1.3 \text{ km s}^{-1}$ ) resolution survey of Dame, Hartmann & Thaddeus (2001) are overlaid on the plots, showing that the structure of the profiles match well, although the intensity of the Mopra line peaks is  $\sim 1.4$  times higher than the corresponding Dame, Hartmann & Thaddeus (2001) intensities (see Table 2). The intensity ratio was determined using the average spectra for each square

**Table 2** The median and mode of the ratio of the Mopra CO intensities to those of the Dame, Hartmann & Thaddeus (2001) survey, calculated using the average spectra in each square degree over the velocity range  $v = [-120, 20] \text{ km s}^{-1}$ .

Cube	Median	Mode
G320	1.42	1.40
G321	1.31	1.27
G322	1.28	1.28
G323	1.42	1.37
G324	1.62	1.61
G325	1.41	1.37
G326	1.34	1.31
G327	1.38	1.27
G328	1.64	1.60
G329	1.41	1.37
Average	1.42	1.39

degree over the velocity range  $v = [-120, 20] \text{ km s}^{-1}$  where the majority of the emission lies, and has been found to be relatively consistent across DR1. Wong et al. (2011) found the average of the Mopra extended beam efficiency ( $\eta_{\text{XB}}$ ) had a typical rms deviation of  $\sim 10\%$  over their eight observing seasons (each about a month in duration), with much of the variation reflecting changes in the system temperature scale due to instrument modifications. Their beam efficiencies were lower than those used to calculate  $T_{\text{MB}}$  in this paper; using these would only increase the ratio of the Mopra CO fluxes to those of Dame, Hartmann & Thaddeus (2001).

The integrated intensity maps in Figures 9–11 highlight molecular clouds in the Mopra  $^{12}\text{CO}$  and  $^{13}\text{CO}$  data cubes over each  $10 \text{ km s}^{-1}$  interval between  $-110$  and  $+40 \text{ km s}^{-1}$  in units of  $\text{K km s}^{-1}$ , corrected for the beam efficiency  $\eta_{\text{XB}} = 0.55$ . These have been calcu-

<sup>3</sup><http://www.atnf.csiro.au/computing/software/miriad/>

**Figure 7.** The CO line profiles, averaged over each square degree from  $l = 320\text{--}325^\circ$ , in units of  $T_{\text{MB}}$  (K) (i.e. divided by the telescope efficiency,  $\eta_{\text{XB}} = 0.55$ ). The solid line is  $^{12}\text{CO}$ ; the dotted line is  $^{13}\text{CO}$  (which has been multiplied by 3 and offset by  $-0.5\text{K}$  for clarity); these spectra are binned in velocity by 2 pixels ( $0.2\text{km s}^{-1}$ ). The dot-dashed line is the equivalent  $^{12}\text{CO}$  spectrum from the Dame, Hartmann & Thaddeus (2001) survey, and the vertical dashed lines are the velocities from which contaminating sky emission was removed (see Table 1).

**Figure 8.** Further CO line profiles, averaged over each square degree from  $l = 325\text{--}330^\circ$ , in units of  $T_{\text{MB}}$  (K). Other details are as in Figure 7.

**Figure 9.**  $^{12}\text{CO}$  intensity maps with  $^{13}\text{CO}$  contours in  $\text{K km s}^{-1}$ , corrected for the beam efficiency  $\eta_{\text{XB}} = 0.55$ , from  $v = -110$  to  $-60 \text{ km s}^{-1}$  integrated over  $10 \text{ km s}^{-1}$  intervals. The  $^{13}\text{CO}$  contours are at 5, 15, 25, 35  $\text{K km s}^{-1}$ . Note that the boundary of the survey is evidenced by spots of poor signal to noise along the  $b = +0.5^\circ$  boundary.

lated using the *dilated mask* code developed for the MAGMA survey of the Magellanic Clouds in CO (Wong et al. 2011). The dilated CPROPS mask (Rosolowsky & Leroy 2006) is calculated by identifying regions of high significance ( $> 4\sigma$ ) and expanding these to connected

regions of lower significance ( $> 3\sigma$ ). Masking the data in this way reduces the number of high noise artefacts in the intensity images, although some remain. In particular, the upper boundary of the main survey at  $l = 320\text{--}327^\circ$ ,  $b = +0.5^\circ$  is clearly visible as a series of high noise

**Figure 10.** As per Figure 9,  $^{12}\text{CO}$  intensity maps with  $^{13}\text{CO}$  contours in  $\text{K km s}^{-1}$ , from  $v = -60$  to  $-10 \text{ km s}^{-1}$  integrated over  $10 \text{ km s}^{-1}$  intervals. Note that from the third map the intensity scale differs from Figure 9 due to the weaker fluxes in these velocity ranges, and the  $^{13}\text{CO}$  contours are now at 1, 8, 15, 22  $\text{K km s}^{-1}$ . Due to the weaker signal fluxes there are more localised instances of high noise apparent in the  $^{13}\text{CO}$  contours in this Figure, most obviously the column at  $l \approx 323.8^\circ$  in the lower three maps.

points in both the  $^{12}\text{CO}$  intensity map and the  $^{13}\text{CO}$  contours.

To aid interpretation of the data, Figure 12 shows derived relationships between the radial velocity and

galactocentric radius ( $R$ , left) and the distance from the Sun ( $D$ , right) for the central longitude of each square degree in DR1. This is an expansion of Fig. 9 in Paper I, now showing the variation across the whole ten degrees.

**Figure 11.** As per Figure 10,  $^{12}\text{CO}$  intensity maps with  $^{13}\text{CO}$  contours in  $\text{K km s}^{-1}$ , from  $v = -10$  to  $+40 \text{ km s}^{-1}$  integrated over  $10 \text{ km s}^{-1}$  intervals.

As in that figure, the right plot shows the near-far ambiguity for negative velocities between  $0 \text{ km s}^{-1}$  and the tangent velocity along each sightline (decreasing with  $l$ ). From the intensity maps in Figure 9, it is clear that a number of molecular clouds occur at ‘forbidden’ velocities (possessing velocities that are not possible un-

der the assumption that the rotation curve holds, i.e.  $< -95 \text{ km s}^{-1}$ ); in this analysis any such velocities are assigned to the tangential distance. Clouds with positive velocities have source distances greater than twice the tangent distance.

**Figure 12.** Radial velocity-distance relationships calculated for the centre of each square degree in DR1 using the McClure-Griffiths & Dickey (2007) rotation curve for the inner Galaxy (i.e. negative velocities, with  $R < R_{\odot}$ ) in the fourth quadrant, with the Brand & Blitz (1993) curve for the outer Galaxy (i.e. positive velocities, and scaled to give the same orbital velocity at  $R = R_{\odot}$ ). To the left, the galactocentric radius in kpc is plotted against radial velocity,  $V_{\text{LSR}}$  in  $\text{km s}^{-1}$ . To the right, distance from the Sun,  $D$ , in kpc is plotted against  $V_{\text{LSR}}$ . Near-distance solutions assume  $D < D_{\text{tangent}} \sim 7.0$  kpc. Far-distance solutions are for  $D_{\text{tangent}} < D < 2D_{\text{tangent}}$ .

**Figure 13.**  $^{12}\text{CO}$  position-velocity image for DR1, with the Galactic longitude,  $l$  on the  $x$ -axis, against the  $V_{\text{LSR}}$  radial velocity in  $\text{km s}^{-1}$  on the  $y$ -axis. The data have been averaged over the central degree in latitude; residuals from poor data are evident in the vertical striping. The solid lines are model positions of the centre of the spiral arms in a four-arm spiral galaxy with pitch angle of  $12.5^\circ$ , a central bar length of 3 kpc and a Sun-Galactic centre distance of 8.0 kpc (parameters from Vallée 2014). From the lower edge on the left axis these are: the Norma arm (near at  $-100 \text{ km s}^{-1}$  and far at  $-60 \text{ km s}^{-1}$ ; black dotted line), the Scutum-Crux arm (near; red dot-dashed line), the Sagittarius-Carina arm (near; blue dashed line), the Scutum-Crux arm (far; red dot-dashed line) and the Sagittarius-Carina arm (far; blue dashed line). Only a few clouds are visible in this furthest arm, and only in  $^{12}\text{CO}$  and  $^{13}\text{CO}$ .

Figure 13 shows a position-velocity slice of the  $^{12}\text{CO}$  emission averaged over the primary degree of latitude of the DR1 data cube, overlaid with model positions of the spiral arms in a four-arm spiral galaxy. The parameters of the model galaxy have been taken from Vallée (2014)

and depict a four-arm spiral galaxy with a pitch angle of  $12.5^\circ$ , a central bar length of 3 kpc and Sun-Galactic centre distance of 8.0 kpc. While the molecular clouds clearly lie in striped bands across the position-velocity diagram, the exact centre of the spiral arms is harder

**Figure 14.**  $^{12}\text{CO}$  position-velocity images for DR1, with the Galactic longitude,  $l$  on the  $x$ -axis, against the  $V_{\text{LSR}}$  radial velocity in  $\text{km s}^{-1}$  on the  $y$ -axis. The data in each plot have been averaged over 6 arcmin in latitude, the upper image is centred on  $b = 0.45^\circ$ , the central plot is the midplane  $b = 0^\circ$  and the lower image is centred on  $b = -0.45^\circ$ ; residuals from poor data are evident in the vertical striping.

to determine. The meta-analysis of Vallée (2014) calculated the radius of the spiral arms to be near 400 pc from mid-arm to dust lane, which suggests that it is difficult to identify clearly the arm in which individual clouds reside, particularly in regions such as  $l = 329\text{--}330^\circ$ , where the Norma and Scutum-Crux arms are close in velocity space.

The distribution of molecular clouds with latitude is illustrated in Figure 14, which shows the position-velocity distribution of  $^{12}\text{CO}$  emission vertically averaged over the 6 arcmin surrounding each of  $b = 0^\circ$  and  $b = \pm 0.45^\circ$ . The differences between these images is striking, showing how discrete the molecular gas is even within the Galactic plane. There is very little CO located at the ‘forbidden’ velocities indicated by Figure 12 at  $b = -0.45^\circ$ , while the fastest negative velocities occur at the higher latitudes. It is also worth noting that the vertical streaking, caused by high noise residuals in the data, occurs at different longitudes in the three position-velocity diagrams; these suggest that the methods used to clean high-noise columns work well, although individual pixels with poor baselines may remain.

Figure 15 shows the distribution of mass in DR1, under the assumption that the clouds with negative velocities are located at the near distance (providing a lower limit on the true molecular mass), and that the X-factor used to link the CO intensity to the  $\text{H}_2$  column density is  $X_{\text{CO}} = 2.7 \times 10^{20} \text{ cm}^{-2} (\text{K km s}^{-1})^{-1}$ . This value is adopted for  $|b| < 1^\circ$  using figure 11 of Dame, Hartmann & Thaddeus (2001), and while it is larger than their value of  $X_{\text{CO}} = 1.8 \times 10^{20} \text{ cm}^{-2} (\text{K km s}^{-1})^{-1}$  for  $|b| > 5^\circ$ , it is within the uncertainties recommended by Bolatto, Wolfire & Leroy (2013) in their meta-analysis of X-factor values from observational and theoretical studies of the Milky Way. These simplifications were also adopted in Paper I to provide a lower limit on the molecular mass in G323; however it was also shown that one of the five features in the spectrum was likely misidentified as being at the near distance rather than the far distance. This leads to an underestimate of the total mass of about one quarter, which is within the uncertainty of using a constant X-factor mass calibration.

The mass distribution in Figure 15, while coarse, shows how the lower mass limit for each square degree varies over these  $10^\circ$  in longitude. The contributions to the total mass per degree from clouds at positive (far distances) and negative (nearer) velocities can be related to features in the position-velocity diagram in Figure 13. In particular, the lines of sight through  $l = 324\text{--}326^\circ$  possess a large component of mass at positive velocities, arising from the clouds at  $+35 \text{ km s}^{-1}$  from the far Sagittarius-Carina arm (see Figure 11), while the increase at  $l = 320^\circ$  is due to a large cloud at  $v = [-10, +10] \text{ km s}^{-1}$ , which cannot be associated with a single spiral arm using only the CO emission. The mass increases from a minimum at  $l \sim 322^\circ$  of  $\sim 10^6 M_\odot$  to a maximum at  $l \sim 328^\circ$  of  $\sim 5 \times 10^6 M_\odot$ , with a total of  $\sim 4 \times 10^7 M_\odot$  within the  $10^\circ$  main survey span, where  $|b| < 0.5^\circ$ . Of this, approximately 15% is situated beyond the Solar circle.

**Figure 15.** Mass distribution in DR1, calculated from the  $^{12}\text{CO}$  emission per square degree using  $X_{\text{CO}} = 2.7 \times 10^{20} \text{ cm}^{-2} (\text{K km s}^{-1})^{-1}$  (see text). The dotted line is the mass contribution from molecular clouds at negative velocities (assumed to be at the near distance), the dashed line that from positive velocities (sited beyond the Solar circle), and the solid line is the total (all in units of Solar mass).

### 3.1 Sample Science

The principal intention of this paper is to describe the CO data cubes that make up DR1. These may be used for a variety of applications, as they provide the distribution of the molecular gas along a substantive portion of the fourth quadrant of the Galaxy, as well as its dynamical motions. From this, column densities, optical depths and the three dimensional molecular mass distribution can be inferred, such as were outlined above. Comparison with infrared to millimetre-wave continuum images, for instance, would allow star formation efficiencies to be determined, and the variation of the  $X_{\text{CO}}$  conversion factor between CO flux and  $\text{H}_2$  column density to be examined on a galactic scale. Three sample science investigations that have been undertaken using the Mopra CO survey data are illustrated here.

The first compares the CO emission in the G328 region with that of [CI] 809 GHz (from the HEAT telescope in Antarctica) and HI 21 cm (from the Southern Galactic Plane Survey; McClure-Griffiths, et al. 2005) emission, discovering a cold, filamentary molecular cloud nearly  $1^\circ$  in length but only  $5'$  across (Burton et al. 2014). The emission was confined to a narrow ( $2 \text{ km s}^{-1}$  FWHM) velocity range, with the hydrogen seen in self-absorption (i.e. HISA), apparently enveloping the molecular gas. The authors hypothesised that the formation of a molecular cloud was being witnessed, with the molecular material possibly condensing out of the atomic substrate. Further analysis of the entire data cube, not just the narrow velocity range associated with this filament, is now being undertaken to investigate the variation of the [CI] to CO ratio, and to search for evidence of ‘dark’ molecular gas. This is molecular gas where its normal tracer (CO) is weak, or absent

(i.e.  $\text{H}_2$  without CO), so that the molecular gas has not been detected, or at least the amount has been underestimated. However if CO is absent (presumably due to photodissociation by far-UV photons), the carbon will be present as either C or  $\text{C}^+$ . These species emit in the THz spectral regime, where the HEAT telescope operates. Analysis of the complete data set (Burton et al. 2015, in preparation) indicates that at the edges of the molecular clouds there is a tendency for the [CI]/CO ratio to rise, as the CO itself falls, consistent with the existence of dark molecular gas.

The second example relates the Mopra CO data to X-ray emission. A bright X-ray flare was observed from the binary star Circinus X-1 in late 2013 by three spacecraft (*Swift*, *Chandra* and *XMM-Newton*). Over a three month period four well-defined rings were seen in the X-rays, extending outwards with time to a distance of  $14'$  from the central source. This is in the G322 portion of our CO survey. Comparison of the Mopra data with the images from the X-ray satellites showed that each of the X-ray peaks in the rings is correlated with corresponding emission in the molecular gas. However, each has a different velocity, ranging from  $-81$  to  $-32 \text{ km s}^{-1}$  (see Heinz et al. 2015). The X-rays are being scattered off clumps of dust associated with the molecular gas to produce the light echoes. Using the distances to these clumps inferred from the Galactic rotation curve, and the scattering geometry a direct kinematic distance could be determined for the source. This was found to be  $9.4 \text{ kpc}$ , significantly greater than the previously estimated  $4 \text{ kpc}$ . It implies that Circinus X-1 is a frequent super-Eddington source, producing a narrow jet with a collimation angle of  $\theta < 3^\circ$  and a Lorentz beaming factor of  $\Gamma > 22$ .

The final example relates the Mopra CO data to an unidentified radio continuum source known as PMN 1452-5910, thought possibly to be related to an SNR evident at  $843 \text{ MHz}$  from MOST data (Bock, Large & Sadler 1999), as analysed by Jones & Braiding (2015). Three features are apparent in the Mopra CO spectrum towards this source, at  $-50$ ,  $-42$  and  $-1 \text{ km s}^{-1}$ . Their morphology, however, in comparison to that of the radio continuum, suggests that it is the  $-1 \text{ km s}^{-1}$  CO feature that is associated with the radio, so providing a distance to the source. This also identifies the source with an  $\text{H}_2\text{O}$  maser at a similar velocity, and enables an interpretation of infrared images from the Spitzer telescope to be made. Jones & Braiding concluded that the source is a previously-unidentified massive star forming region about  $13 \text{ kpc}$  away. They then determine parameters for the region:  $\sim 2 \times 10^4 M_\odot$  of molecular gas with an average column of  $\sim 10^{21} \text{ cm}^{-2}$ , enclosing several UCHII regions with emission measures  $\sim 10^{6-7} \text{ pc cm}^{-6}$  and electron densities  $\sim 10^3 \text{ cm}^{-3}$ . Three OB stars (2 of type B0, 1 of O8) can account for the radio emission.

## 4 CONCLUSIONS

In their forthcoming Annual Review of molecular clouds in the Milky Way, Heyer & Dame (2015) state: “For further progress in [molecular cloud census studies], surveys comparable to the Galactic Ring Survey (Jackson et al. 2006) in resolution and sensitivity in the fourth quadrant are required.” The first  $10^\circ$  of such a survey have been presented here. The Cherenkov Telescope Array will produce a new survey of the high energy gamma-ray sources in the Galactic plane (Dubus et al. 2013) at a resolution approaching 1 arcminute (Bernlöhr et al. 2013). High resolution molecular gas surveys such as this will be required to properly identify these sources amongst the diffuse TeV gamma-ray emission components CTA will likely detect (e.g. Acero et al. 2013). The Mopra CO survey of the southern Galactic plane aims to address these community needs by observing the entirety of the fourth quadrant along the plane from  $l = 270\text{--}360^\circ$  where  $|b| < 0.5^\circ$ , at a spatial resolution of 35 arcsec and a spectral resolution of  $0.1 \text{ km s}^{-1}$ , in the  $J = 1\text{--}0$  lines of  $^{12}\text{CO}$ ,  $^{13}\text{CO}$ ,  $\text{C}^{18}\text{O}$  and  $\text{C}^{17}\text{O}$ . This is a significant improvement over previous studies conducted of the fourth quadrant of the Galaxy.

Data Release 1 from the Mopra CO survey covers the 11.5 square degrees from  $l = 320\text{--}330^\circ$ ,  $b = \pm 0.5^\circ$  and  $l = 327\text{--}330^\circ$ ,  $b = +0.5\text{--}1.0^\circ$ . Included in this paper are a number of metrics describing the quality of the dataset, which has a typical rms noise of  $\sim 1.3 \text{ K}$  in the  $^{12}\text{CO}$  frequency band and  $\sim 0.5 \text{ K}$  in the other isotopologue frequency bands, and a discussion of the improvement in the data taken during the winter months compared to the initial square degree observed in summer that was published in Paper I. The line intensities in the Mopra CO survey are  $\sim 1.4$  times those of the Dame, Hartmann & Thaddeus (2001) survey, and our higher resolution CO line profiles match those of their survey quite well. Sample line profiles for each square degree are presented, as well as integrated intensity maps that show the filamentary nature and complexity of the molecular clouds in the survey. The primary  $10^\circ \times 1^\circ$  strip of the Galactic plane in DR1 has been found to contain  $\sim 4 \times 10^7 M_\odot$  of molecular gas.

The Mopra CO survey is ongoing, with the intention of covering the entirety of the fourth quadrant of the Galactic plane by the end of 2015. The data are being made available at the survey website<sup>4</sup>, and in the CSIRO-ATNF data archive<sup>5</sup>, as they are published.

## 5 ACKNOWLEDGEMENTS

The Mopra radio telescope is currently part of the Australia Telescope National Facility. Operations support was provided by the University of New South Wales and the

University of Adelaide. Many staff of the ATNF have contributed to the success of the remote operations at Mopra. We particularly wish to acknowledge the contributions of David Brodrick, Philip Edwards, Brett Hiscock, Balt Indermuehle and Peter Mirtschin. The University of New South Wales Digital Filter Bank used for the observations with the Mopra Telescope (the UNSW-MOPS) was provided with support from the Australian Research Council (ARC). We also acknowledge ARC support through Discovery Project DP120101585.

Finally, we thank the anonymous referee whose thoughtful comments have improved the clarity and accessibility of this paper.
