ABSTRACT

Objective To determine the contribution of respiratory syncytial virus (RSV) to the subsequent development of severe asthma in different subgroups of children at risk of severe RSV disease.

Settings The study was conducted in New South Wales (NSW), Australia.

Participants The study comprised all children born in NSW between 2000 and 2010 with complete follow-up till 31 December 2011. The cohort was divided into three subgroups: (1) non-Indigenous high-risk children: non-Indigenous children born preterm or born with a low birth weight; (2) Indigenous children: children of mothers whose Indigenous status was recorded as Aboriginal and/or Torres Strait Islander and (3) non-Indigenous standard risk children: all other non-Indigenous term children.

Primary outcome measure Risk of development of severe asthma in different subgroups of children who had RSV hospitalisation in the first 2 years of life compared with those who did not.

Design We performed a retrospective cohort analysis using population-based linked administrative data. Extended Cox model was used to determine HR and 95% CI around the HR for first asthma hospitalisation in different subgroups of children.

Results The cohort comprised 847 516 children born between 2000 and 2010. In the adjusted Cox model, the HR of first asthma hospitalisation was higher and comparable across all subgroups of children who had RSV hospitalisation compared with those who did not. The HR (95% CI) was highest in children aged 2–3 years; 4.3 (95% CI 3.8 to 4.9) for high-risk, 4.0 (95% CI 3.3 to 4.8) for Indigenous and 3.9 (95% CI 3.7 to 4.1) for non-Indigenous standard risk children. This risk persisted beyond 7 years of age.

Conclusion This large study confirms a comparable increased risk of first asthma hospitalisation following RSV disease in the first 2 years of life across different subgroups children at risk.

Strengths and limitations of the study

- To our knowledge this is the first study to demonstrate increased risk of first asthma hospitalisation following severe respiratory syncytial virus (RSV) disease concurrently in different subgroups of high-risk children at a population level.
- The study cohort comprised all children born in New South Wales between 2000 and 2010 which enabled us to determine the risk of asthma in different age groups extending beyond 7 years.
- This was an epidemiological study using linked administrative data and lacked information relating to factors like atopic predisposition and risk of subsequent asthma in this cohort, hence a causal association cannot be established for RSV hospitalisation.

INTRODUCTION

Background

Globally, acute lower respiratory infections (ALRIs) are a major cause of childhood morbidity and mortality.¹ Early life respiratory viral infections have been linked to the development of subsequent asthma in children.² This link has been particularly highlighted for early respiratory syncytial virus (RSV) infection in children which continues to be the major viral cause of childhood ALRIs in the first 2 years of life.³ It has been proposed that severe RSV infection in early childhood is associated with impaired lung function which persists beyond childhood and increases risk of recurrent wheezing and asthma at a later age of life.^{4 5} Asthma symptoms associated with severe RSV illness in first year of life can even persist in early adulthood.⁶ In addition,

early RSV hospitalisation may also result in reduced lung function, even in the absence of asthma symptoms.⁶ Although there is some evidence that severe RSV disease and allergic sensitisation may be linked via interleukin (IL)-13/IL-4 gene polymorphisms, severe RSV infection in early childhood is possibly a consequence rather than a cause of a predisposition to severe reversible airway diseases.^{7,8}

Objectives

Australia has a high prevalence of paediatric asthma compared with other developed countries.^{9,10} It is estimated that 21% of Australian children aged 0–15 years have had a previous diagnosis of asthma, with 11% having a current diagnosis of asthma.¹¹ In 2014, >13 000 children aged 1–17 years presented to New South Wales (NSW) emergency departments for asthma, representing two-thirds of all hospital presentations across the state and yielding a significant burden on the healthcare system.¹² The burden of RSV-associated lower respiratory tract infection (LRTI) is also very high in NSW, especially in children aged <2 years with an average annual direct healthcare cost of more than AUD 9 million in NSW alone.¹³ In addition, our previous study has demonstrated that the incidence of severe RSV disease was exceptionally high among children who were born preterm or with bronchopulmonary dysplasia and Indigenous children of NSW.¹³ It is, therefore, important to determine what, if any, contribution early severe RSV disease has on subsequent asthma hospitalisations in these subgroups of children at risk. While data exist on the high burden of RSV disease in these subgroups of children, to our knowledge, no study has investigated the contribution of RSV to subsequent asthma risk in different high-risk paediatric populations simultaneously. Such information will be important to inform targeted public health interventions aimed to lower the burden of severe asthma in Australian children.

To address this knowledge gap, we conducted a retrospective population-based cohort study designed to investigate the role of early RSV ALRI on the subsequent risk of development of severe asthma in different subgroups of children at risk in NSW.

METHODS

Study design

The study was a retrospective cohort analysis using linked population-based administrative data.

Study site and study population

The study was conducted in NSW, Australia comprising all children who were born in NSW born between 2000–2010 with complete follow-up till end of December 31st 2011. Each child was included from birth through the end of the follow-up period or in-hospital death, whichever was earlier. The birth cohort was divided into three subgroups:

1. Non-Indigenous high-risk children: Non-Indigenous children who (i) were born preterm (gestational age (GA) <37 weeks), (ii) were born at term with a birth weight of <2500 g.
2. Indigenous children: Children of mothers whose Indigenous status was recorded as Aboriginal and/or Torres Strait Islander in any of the data sets were considered to be Indigenous, including any born preterm or born with low birth weight.
3. Non-Indigenous standard risk children: All other non-Indigenous term children.

Variables

Exposure variables

The main exposure variable of interest was any episode of RSV coded hospitalisation in the cohort child from birth to 2 years of age, the peak age group for RSV hospitalisations.¹³ The International Classification of Diseases, 10th edition (ICD-10) primary diagnostic codes were used to identify RSV hospitalisations. Any hospitalisation with primary diagnostic codes associated with RSV pneumonia (J12.1), acute RSV bronchitis (J20.5), acute RSV bronchiolitis (J21.0), unspecified ALRIs (J22), unspecified acute bronchitis (J20.9) and unspecified acute bronchiolitis (J21.9) identified during RSV season (April–September in NSW) were included as RSV hospitalisations.

Outcome variable

The outcome variable of interest was first episode of asthma hospitalisation beyond the age of 2 years until the end of follow-up. All hospitalisations with primary diagnostic codes associated with asthma (J45), predominantly allergic asthma (J45.0), non-allergic asthma (J45.1), mixed asthma (J45.8), asthma unspecified (J45.9) and status asthmaticus (J46) or wheeze (R0.62) were considered as asthma hospitalisations.

Confounders

Confounders included in the analysis were based on the published literature and included maternal and child factors.¹⁴ Maternal variables were age at birth of the cohort child, parity, smoking during pregnancy and index of socioeconomic disadvantage of the mother's residential postcode at birth. Child factors included in the analyses were season of birth and sex of the child.

Data sources

The Centre for Health Record Linkage (CHeReL) (<https://www.cherel.org.au>) in NSW conducts linkage of various administrative health datasets for research purposes. CHeReL follows best practice probabilistic linkage¹⁵ to combine personal information to produce a person-based dataset using the NSW Perinatal Data Collection as the primary dataset to which all other datasets are linked. Each child was assigned a Patient Project Number and this was attached to the records in each source database. All other personal identifiers were removed from each of the datasets and the de-identified datasets with the unique identifier key were provided to

the study investigators. One of the study investigators (NH) combined records of the same child in the different data sets using the unique identifier key and undertook data cleansing.

The cohort was identified from the NSW Perinatal Data Collection in which all births in NSW are registered. Data relating to any episode of RSV and asthma in the cohort children were retrieved from the Admitted Patient Data Collection. This dataset also contained outcome of each hospitalisation including discharge status, death and need for transfer. The corresponding maternal, perinatal and sociodemographic factors for the cohort children were retrieved from the Perinatal Data Collection which was linked to the Admitted Patient data Collection. Socio-economic disadvantage based on maternal post code of residence at the time of birth of the cohort child was measured using the Socioeconomic Index of Areas and Indices of Relative Socioeconomic Advantage and Disadvantage from the Australian Bureau of Statistics.¹⁶

Bias

This was a large whole-of-population based cohort study based on almost complete data sets. Out of 1 264 943 observations, there were 7432 (0.5%) observations with one or more variables missing which were excluded from the final analyses.

Study size

This was a whole-of-population study including all children born in NSW between 2000 and 2010 so we did not perform any sample size calculation for our study.

Quantitative variables

The maternal age at birth of the cohort child was divided into five age groups including <20 years, 20–24 years, 25–29 years, 30–34 years and ≥35 years; age group 25–29 years was considered as the referent group. IRSAD was divided into quintiles from least to most advantaged where level one was most disadvantaged and level five was most advantaged and level one was considered as the referent group.¹⁶

Statistical analyses

This was a cohort study where children were followed from birth and the risk of subsequent first asthma hospitalisation beyond the age of 2 years was determined using hazard analyses taking age of the child at asthma hospitalisation as the relevant time to event. As the hazard of subsequent asthma hospitalisation was non-proportional violating the proportionality hazard assumption of standard Cox model, we used an extended Cox model with time varying covariate to account for the non-proportionality. The age at asthma hospitalisation was split into 2–3 years, 3–5 years, 5–7 years and >7 years age groups and the interaction between baseline RSV risk and subsequent asthma hospitalisation was examined for the different age groups. Separate models were constructed for each of the predefined subgroup of children. The final multivariable model was adjusted for all available confounders

mentioned in the method section. We estimated the HR and the 95% CIs around the HR of first asthma hospitalisation after the age of 2 years for children with versus without any RSV hospitalisation in their first 2 years of life.

RESULTS

Profile of the cohort

The cohort comprised 847 516 children born between 2000 and 2010. Of these, 437 034 (52%) were men and the mean age of the cohort at the end of the follow-up period was 73 months (SD ±42 months) (table 1). In total, 31 831 (4%) cohort children had at least one episode of RSV hospitalisation before the age of 2 years, of which 2405 (7.5%) also had an episode of asthma hospitalisation after the age of 2. The median age at first asthma hospitalisation was 3.2 years (IQR 2.5–4.4 years).

Hazard for asthma hospitalisation

In the adjusted multivariable Cox hazard model, the hazard of first asthma hospitalisation persisted to be double beyond the age of 7 years for children who were hospitalised with RSV in the first 2 years of life compared with those who were not (table 2). The adjusted HR for first asthma hospitalisation was highest for children between the ages 2 and 3 years. The adjusted HR at ages 2–3 years for non-Indigenous standard risk children was 3.9 (95% CI 3.7 to 4.1), for high-risk children was 4.3 (95% CI 3.8 to 4.9) and for Indigenous children was 4.0 (95% CI 3.3 to 4.8). The risk of asthma hospitalisation at different ages was comparable across the different subgroups of children.

DISCUSSION

To our knowledge this is the first study to demonstrate increased risk of first asthma hospitalisation following severe RSV disease in different subgroups of high-risk children concurrently. Our findings, based on a very large population cohort of children followed up to 11 years of age, suggest that different subgroups of high-risk children, who developed RSV disease within the first 2 years of life continue to be at elevated risk of first asthma hospitalisation beyond the age of 7 years. The HR of first asthma hospitalisation was similar across all subgroups of children with the HR being four times higher at ages 2–3 years. Although premature children and Indigenous children aged <2 years are at almost 10 times higher risk of acquiring severe RSV disease compared with standard risk children,¹³ the similar hazard of subsequent asthma hospitalisation across different subgroups of children suggest that RSV might be the strongest predictor for developing subsequent severe childhood asthma. Thus, RSV might not only be the main aetiology for acute respiratory illness but also be an important contributor to chronic respiratory morbidity in children suggesting that interventions/therapies to prevent early severe RSV disease will help reduce the burden of subsequent paediatric

asthma/wheeze. While there are no effective antivirals or vaccines against RSV disease, at present, there is an effective anti-RSV monoclonal antibody (palivizumab) which can prevent severe RSV disease in high-risk infants including those born preterm and with chronic lung and heart conditions.^{17 18} Studies have shown that palivizumab can also prevent subsequent recurrent wheeze in preterm children.^{19 20} However, use of palivizumab remains limited in Australia and there is no standardised national guideline. Considering the potential beneficial effect of palivizumab on severe RSV diseases and subsequent recurrent wheeze in children, there is a need for revisiting its effectiveness and standardising guidelines with inclusion of Indigenous children as high-risk.

The risk of first asthma hospitalisation in our cohort children who had severe RSV disease leading to

hospitalisation in their first 2 years of life was significantly higher across all the age strata. It is possible that many of the first asthma hospitalisation within ages 2–3 and 3–5 years in our analysis may have been due to recurrent wheeze. Indeed diagnosis of asthma in children aged <5 years is challenging. The Global Initiative for Asthma guideline suggest that symptoms including frequent episodes of wheeze, activity-induced cough or wheeze, nocturnal cough without viral infections in periods which persist beyond 3 years of age are suggestive of asthma in children <5 years of age.²¹ In addition, RSV disease has been associated with increased risk of persistent wheezing in children.^{5 22} However, the risk of first asthma hospitalisation in this cohort was also significantly higher at ages 5–7 years and beyond 7 years of age. Another longitudinal study done in the UK had also reported that the odds

of doctors diagnosed asthma beyond the age of 7 was double for children who had RSV hospitalisation in the first year of life compared with the those who did not.²² Other studies have also noted that risk of subsequent asthma following early RSV illness can persist until 11 years of age⁵ and even in adulthood.⁶ It is believed that early severe lower RSV infection may cause airway remodelling and impair development of the growing lung which persists in later life.²³ Even mild RSV disease may lead to residual impaired lung function in children up to the age of 13 years.⁵

An important limitation of the study is that our exposure and outcome variables of interest were coded RSV and asthma hospitalisations; it is possible that some hospitalisations were misclassified because routine laboratory confirmation of RSV may not be a standard clinical practice in some hospitals and the diagnosis of asthma in younger children is a challenge. This was a population-based study using administrative data where diagnosis of diseases was based on ICD codes and any possible error with the coding system was beyond our control. We considered all unspecified episodes of bronchiolitis and bronchitis identified during RSV season which may have led to overestimation or underestimation (as laboratory confirmation of RSV diseases is not necessarily a standard clinical practice) of the effect. However, our previous analysis¹³ suggests that all-cause-associated ALRI-coded hospitalisations in children aged <2 years during the RSV season follows a similar trend as RSV coded hospitalisation and RSV notification data which suggests that most paediatric ALRI hospitalisations during the RSV season are likely due to RSV. We did not have access to any information regarding atopic predisposition of children; it is likely that many children hospitalised with asthma were atopic. If early severe RSV disease is also a manifestation of atopic predisposition, it is possible that the observed relationship between RSV and asthma is not causal. However, other studies suggest that the

association between asthma and RSV is independent of atopic history.^{24 25} As this was an epidemiological study, causality of the association between RSV and asthma cannot be confirmed, but the findings are comparable to other studies adding to the body of evidence that a strong association exists. We did not have access to ambulatory care data so could not assess the association between less severe forms of RSV infection and asthma not requiring hospitalisation. In our cohort, there were only 335 hospitalisations coded as associated with any other viral ALRI in the first 2 years of life, compared with 31 831 RSV-associated ALRI hospitalisations; we therefore did not investigate association between other virus-specific ALRI and asthma. This work compliments the apparent association between RSV disease with the subsequent development of asthma,⁵ while infections with other viruses like rhino and influenza viruses²⁶ are more clearly associated with exacerbations of asthma. In addition, even if any association exist, their contribution to asthma is likely to be comparatively small.

Our study confirms that hospitalisation for severe RSV disease in the first 2 years of life is associated with the subsequent hospitalisation for first episode of asthma hospitalisation in Australian children. While there are currently no effective antivirals or vaccines targeting RSV, several vaccines are being evaluated in clinical trials.²⁷ Once an effective vaccine becomes available, long-term follow-up of children to evaluate the impact on subsequent asthma development will help define the causal pathway of RSV and asthma, particularly in the high-risk groups. Meanwhile, more conservative preventive strategies such as frequent hand washing²⁸ targeted to prevent transmission of RSV disease may also have the added benefit of reducing the burden of asthma in children.
