8

9   **SUMMARY**

10   Isostatic gravity anomalies provide a measure of the Earth's gravity field free from the

11   gravitational attractions of the topography and its isostatic compensation, most commonly

12   represented by a variation in the depth of a compensating density contrast, for example the

13   Moho. They are used by both geodesists and geophysicists alike, though often for different

14   purposes. Unfortunately though, the effect of subsurface loading on the lithosphere renders

15   transfer function (admittance) methods unusable when surface and subsurface loads coexist.

16   Where they exist, subsurface loads are often expressed in the Bouguer anomaly but not in the

17   topography, and it is shown here that this phase disconnect cannot be faithfully represented

18   by either real- or complex-valued analytic admittance functions. Additionally, many studies

19   that employ the isostatic anomaly ignore the effects of the flexural rigidity of the lithosphere,

20   most often represented as an effective elastic thickness (T_e), and assume only Airy isostasy,

21   i.e. surface loading of a plate with zero elastic thickness. The consequences of such an

22   omission are studied here, finding that failure to account for flexural rigidity and subsurface

23   loading can result in (1) over- or underestimates of both inverted Moho depths and dynamic

24   topography amplitude, and (2) underestimates of the size of topographic load that can be

25   supported by the plate without flexure. An example of the latter is shown over Europe.

26 Finally, it is demonstrated how low values of the isostatic anomaly variance can actually be

27 biased by these anomalies having low power at the long wavelengths while still possessing

28 high power at middle to short wavelengths, compared to the corresponding Bouguer anomaly

29 power spectrum. This will influence the choice of best-fitting isostatic model if the model is

30 chosen by minimization of the isostatic anomaly standard deviation.

33 Dynamics of lithosphere and mantle; Lithospheric flexure.

34

35 **1 INTRODUCTION**

36 According to the principle of isostasy, topographic features on the Earth's surface must be

37 compensated to some extent by subsurface mass-density anomalies, as in Archimedes'

38 principle. The simplest models of isostatic compensation are the Airy-Heiskanen (Airy 1855;

39 Heiskanen 1931) and Pratt-Hayford (Pratt 1855; Hayford 1909) (e.g. Heiskanen & Moritz

40 1967; Watts 2001). The Airy-Heiskanen (or just 'Airy') model compensates variations in

41 topography by variations in the relief of the crust-mantle interface (the Moho) about a mean

42 compensation depth, where the crust and mantle have spatially uniform densities; for

43 example, higher topography has a thicker crust below it. In the Pratt-Hayford (or just 'Pratt')

44 model, topographic variations are compensated by lateral variations in crustal density, with a

45 flat compensation depth (Moho), so that higher topography is modelled as having lower

46 density relative to its surroundings. These two models are commonly called 'local isostasy' to

47 distinguish them from the regional isostatic model of compensation, originally proposed by

48 Vening Meinesz (1931).

49

50   The regional model is similar to the Airy model in that compensation is achieved by

51   deflection of the Moho, where the density of the crust is constant. The difference between

52   them lies in the flexural rigidity (D) of the crust and its ability to support loads mechanically.

53   In the Airy model, the crust has no such mechanical strength ($D = 0$); a point surface

54   topographic load is compensated by deflection of the Moho directly underneath it and

55   nowhere else. In the Vening Meinesz model ($D > 0$), the stresses caused by the point load are

56   regionally distributed about the point, and the load is both compensated by the Moho

57   deflection, and supported by the mechanical strength of the crust; the Moho deflection is thus

58   less than it would be under Airy isostasy. Modern interpretations of the Vening Meinesz

59   model discuss the flexure of the elastic portion of the lithosphere, being the crust and

60   uppermost mantle, or portions thereof, rather than the crust alone, where the lithosphere

61   'floats' on an inviscid asthenosphere (e.g. Watts 2001). In most models, the primary density

62   contrast providing compensation of loads is still assumed to lie at the Moho (e.g. Forsyth

63   1985), since the density contrast at the lithosphere-asthenosphere boundary is an order of

64   magnitude smaller, ~40 kg m^{-3} as opposed to ~500 kg m^{-3} at the Moho (Cordell *et al.* 1991).

65

66   These isostatic compensation mechanisms can be used to apply corrections to gravity

67   anomalies by modelling and removing the gravity effect of the subsurface mass-density

68   anomalies compensating the topography. In the Pratt model this will be the gravity effect of

69   the lateral density variations in the crust; in the Airy and Vening Meinesz models the

70   correction will model the density anomalies caused by deflection of the Moho; while the

71   Vening Meinesz model must also account for the fact that mechanical support implies a

72   shallower compensation depth. When the isostatic correction thus derived is subtracted from

73   the Bouguer anomaly the result is the isostatic anomaly, which should be small if the model

74   is a fair description of the actual compensation and its parameters, and the Bouguer

75 correction and/or topographic reduction have properly accounted for the presence of any

76 mass-density anomalies above the geoid.

77

78 Non-zero isostatic anomalies show that the actual compensation mechanism differs from that

79 of the assumed model. Such differences can be attributed to relatively minor concerns such as

80 incorrect choice of densities or compensation depths in the model, or major concerns such as

81 a wrong choice of model where the effects of mechanical or dynamic support are

82 misinterpreted as under- or overcompensation in a local isostatic model (e.g. Simpson *et al.*

83 1986). However, non-zero isostatic anomalies can also reveal compensated intralithospheric

84 density anomalies with no topographic expression; regional variations in effective elastic

85 thickness (T_e), or loading at one value of T_e followed by erosional unloading at another;

86 mantle density variations and the dynamic support of the lithosphere due to convective

87 processes in the upper mantle; the viscoelastic response to time-varying loads, such as glacial

88 isostatic adjustment; and the deeper signals from the mantle and core (e.g. Forsyth 1985;

89 Simpson *et al.* 1986; Ussami *et al.* 1993; Kaban *et al.* 2004).

90

91 Geophysicists have largely used isostatic anomalies for investigations of Earth structure.

92 Some of these studies have assumed Airy isostasy when computing isostatic anomalies (e.g.

93 Karner & Watts 1982; Simpson *et al.* 1986; Ussami *et al.* 1993; Kaban *et al.* 1999; Tiwari *et*

94 *al.* 2003). Other workers have invoked the flexural rigidity (or its geometric analogue, the

95 effective elastic thickness, T_e) in isostatic anomaly computation (e.g. Walcott 1970; Dorman

96 & Lewis 1972; Karner & Watts 1983; Watts *et al.* 1995; Jordan & Watts 2005; Harmon *et al.*

97 2006; Wyer & Watts 2006; Watts & Moore 2017). Several studies have sought to estimate

98 lithospheric parameters such as interface depths and densities by minimizing the isostatic

99 anomaly variance (e.g. Sünkel 1985; Martinec 1993, 1994a,b; Kaban *et al.* 2004; Sjöberg

100   2009; Bagherbandi & Sjöberg 2012), a topic that will be investigated in Section 3.

101   Additionally, many studies assume Airy isostasy when computing dynamic topography (e.g.

102   England & Molnar 2015; Molnar *et al.* 2015), a topic that will be addressed in Section 4.3.

103

104   In the geodetic community, however, workers have largely persisted with Airy, and to a

105   lesser extent Pratt models of local isostasy (e.g. Pavlis & Rapp 1990; Martinec 1994b;

106   Balmino *et al.* 2012; Hirt *et al.* 2012; Aitken *et al.* 2015), often because their analyses

107   concern very large, even global study areas where Airy or Pratt models would be more

108   appropriate in describing isostasy than regional models. However, the inability of the Airy

109   model to correctly represent the actual state of compensation is well documented. For

110   instance, Lewis & Dorman (1970) and Dorman & Lewis (1972) assumed Airy isostasy and

111   inverted an isostatic response function to find the density contrasts compensating the North

112   American topography. In addition to the expected shallow positive density contrast their

113   model required an unrealistic negative density contrast (i.e., a decrease in density with depth)

114   within the upper mantle (~400 km depth). Banks *et al.* (1977) adequately remodelled Dorman

115   & Lewis's (1972) data using a regional compensation model with a non-zero elastic

116   thickness, concluding that any local model with negative densities can be replaced by a

117   regional model with compensating positive densities at shallower depths (Banks *et al.* 1977;

118   Simpson *et al.* 1986; Cordell *et al.* 1991).

119

120   Oceanic lithosphere provides cases where local isostasy does not apply. As Sünkel (1985)

121   notes, oceanic crust is typically 7 km thick on average but much deeper compensation levels

122   are required to prevent the oceanic antiroots of the Airy model extending above the seafloor

123   (e.g. Rapp 1982). In contrast, the mechanical support provided by regional isostatic models

124   enables compensation levels to be placed at much more realistic depths, closer to the Moho.

125 For example, Louden & Forsyth (1982) analysed the compensation of the Kane fracture zone,

126 and where the Airy model required a 30 km thick oceanic crust, a flexural model with a more

127 realistic 6 km thick crust gave a better fit to observed admittance data. Nevertheless, Pratt-

128 style compensation is thought to apply at mid-ocean ridges, though with the density increase

129 away from the ridge occurring in the sub-crustal mantle rather than the crust, while Airy

130 isostasy would apply at continent-ocean boundaries (Watts 2007).

131

132 And recently, using spherical harmonics, Watts & Moore (2017) fitted two isostatic models

133 to the mid- to high-degrees ($12 \leq n \leq 400$) of the global EGM2008 free air anomaly (Pavlis *et*

134 *al.* 2012). When using an Airy model the best fit was provided by an unrealistic

135 compensation (Moho) depth of 61 km. In contrast, a better fit was obtained with a flexural

136 model of compensation depth 30 km and $T_e = 34$ km.

137

138 Hence, this study aims to test the limits of the applicability of the Airy isostatic compensation

139 model, but also comments on the utility of isostatic gravity anomalies in general. In Section 2

140 some theory is presented regarding the computation of isostatic anomalies. In Section 3,

141 synthetic Bouguer anomaly and topography models are generated with known plate

142 parameters (such as compensation depth, elastic thickness, etc.); isostatic anomalies are then

143 computed from these synthetic models over a whole range of plate parameters, using the

144 spectral methods described in Section 2. In this fashion many assumptions regarding isostatic

145 models and gravity anomalies can be tested. Section 4 then discusses the implications of the

146 findings in Section 3, but also comments on the isostatic and dynamic support of surface

147 topography in the context of Airy versus flexural isostasy.

148

149 **2 ESTIMATION OF ISOSTATIC GRAVITY ANOMALIES**

2.1 Methods favoured by geophysicists

The isostatic anomaly (Δg_I) is the difference between the Bouguer anomaly (Δg_B) and the gravitational attraction of the compensation model (δg_C):

$$\Delta g_I = \Delta g_B - \delta g_C \qquad (1)$$

Dorman & Lewis (1970) proposed that the Earth acts as a linear filter, and given an observed (post-flexural) topography, h, it was possible to determine the gravitational effect of the isostatic compensation of that topography by filtering the topography with an 'isostatic response function', q. In the 1-D Cartesian space (x) domain they wrote

$$\delta g_C(x) = q(x) * h(x) \qquad (2)$$

where the * indicates space-domain convolution. Hence, by the convolution theorem:

$$\delta g_C(x) = \mathbf{F}^{-1}\left[Q(k)H(k)\right] \qquad (3)$$

where $\mathbf{F}^{-1}$ is the inverse Fourier transform operator, k is wavenumber (spatial frequency), and $Q = \mathbf{F}[q]$ is the admittance which is the wavenumber-domain transfer function from topography to gravity, discussed below. Thus, eq. (1) can be written as

$$\Delta g_I = \Delta g_B - \mathbf{F}^{-1}\left[Q H\right] \qquad (4)$$

While Dorman & Lewis (1970) called Δg_I the "geologic effect", Lewis & Dorman (1970) identified it with the isostatic anomaly, as did Watts (1978), McNutt (1980), Simpson *et al.* (1986), and Kaban *et al.* (1999), who all used such transfer function techniques. Lewis & Dorman (1970) also tested eq. (2) for non-linear terms in the topography, h, by correlating the resultant isostatic anomaly with terms h^n, for $n = 2 - 5$, finding insignificant correlation in their North American study area.

Using equations of flexure and Parker's (1972) formula, one can derive analytic equations for the theoretical admittance for many loading models, for use in eq. (4) (e.g. Kirby 2014).

174   Those considered in this study are described next. The expression for the Bouguer admittance

175   for Airy isostasy is:

176     $Q_A(k) = -2\pi \mathcal{G} \Delta \rho_0 e^{-k z_m}$ (5)

177   (e.g. Forsyth 1985; Watts 2001) where $\mathcal{G}$ is the gravitational constant (Table 1), z_m is the

178   depth to the compensating interface (commonly assumed to be the Moho), and $\Delta \rho_0 = \rho_c - \rho_f$

179   where ρ_c is the density of an incompressible single-layer crust and ρ_f is the density of the

180   overlying fluid, either air or water.

181

182   More general loading models consider the flexural rigidity of the lithosphere, D, which is

183   most commonly expressed in terms of an effective elastic thickness (T_e) where

184     $D = \dfrac{E T_e^3}{12\left(1 - \nu^2\right)}$ (6)

185   (e.g., Watts 2001) and where E is Young's modulus and ν is Poisson's ratio (see Table 1 for

186   the values of these constants). The elastic lithosphere may include numerous crustal layers

187   and the uppermost mantle, depending on the tectonic regime and rheological properties of

188   these strata (Burov & Diament 1995). Although most flexural models place the depth of

189   compensation at the Moho (being a compositional boundary with a large density contrast),

190   the elastic lithosphere may extend into the uppermost mantle where its boundary with the

191   underlying asthenosphere is rheological in nature (with a much lower density contrast as

192   noted in Section 1). It should be noted that T_e does not, in general, describe a physical

193   thickness or depth – rather it is a geometric analogue of the flexural rigidity – though under

194   certain conditions, T_e can equal the mechanical thickness of the lithosphere (e.g. Burov &

195   Diament 1995).

196

197   Banks *et al.* (1977) derived an expression for the Bouguer admittance corresponding to initial

198   subaerial loading on the surface of a plate with non-zero flexural rigidity ('surface' or 'top

199   loading'):

200    $$Q_T(k) \;=\; -2\pi \mathcal{G} \Delta\rho_0 e^{-kz_m} \left(1 + \frac{Dk^4}{g\Delta\rho_1}\right)^{-1} \;=\; -2\pi\mathcal{G}\Delta\rho_0 e^{-kz_m}\, \xi(k)^{-1} \qquad (7)$$

201   where g is the gravity acceleration, $\Delta\rho_1 = \rho_m - \rho_c$, and ρ_m is the density of an inviscid mantle

202   underlying the crust. Eq. (7) defines the variable $\xi(k)$. Surface loading constitutes an initial

203   load emplaced at the Earth's topographic surface by, for example, orogenesis or volcanism. A

204   second flexural model considers loading that takes place within the lithosphere, for instance,

205   from magmatic underplating, igneous intrusions, or during sedimentary basin formation.

206   McNutt (1983) derived a Bouguer admittance equation describing the case when initial

207   loading occurs within the plate ('subsurface' or 'bottom loading'):

208    $$Q_B(k) \;=\; -2\pi\mathcal{G}\Delta\rho_0 e^{-kz_m}\left(1 + \frac{Dk^4}{g\Delta\rho_0}\right) \;=\; -2\pi\mathcal{G}\Delta\rho_0 e^{-kz_m}\,\phi(k) \qquad (8)$$

209   which defines the variable $\phi(k)$.

210

211   Forsyth (1985) unified the surface and subsurface loading regimes by assuming independence

212   of the initial loading processes. From his formulation an expression for the 'combined

213   loading' Bouguer admittance can be derived:

214    $$Q_{TB}(k) \;=\; -2\pi\mathcal{G}\Delta\rho_0 e^{-kz_m}\left(\frac{\xi + \phi f^2 r^2}{\xi^2 + f^2 r^2}\right) \qquad (9)$$

215   (e.g. Ito & Taira 2000) where $r = \Delta\rho_0 / \Delta\rho_1$, and where $f(k)$ is the ratio of the initial

216   subsurface to surface load amplitudes (Forsyth 1985). Considering uniform (wavenumber-

217   independent) values of f, when $f = 0$ eq. (9) becomes eq. (7) and describes surface-only initial

218   loading; when $f \to \infty$, eq. (9) becomes eq. (8) and describes subsurface-only initial loading. In

219   practice, $f(k)$ is computed from the recovered initial loads in Forsyth's (1985) method of T_e

220   estimation, though a uniform value of f can be used in theoretical analytic admittance

221   equations such as eq. (9) (e.g. Kirby 2014). Note that when $T_e = 0$ km, the parameters ξ and

222   ϕ, eqs (7) and (8), both equal 1 and the combined admittance, Q_{TB} in eq. (9), reduces to the

223   Airy admittance formula, eq. (5), showing that the effects of surface and subsurface loading

224   upon a zero-rigidity plate are indistinguishable.

225

226   **2.2 Methods favoured by geodesists**

227   In the geodetic community, the problem is typically framed in terms of a spherical harmonic

228   expansion of the topography, with derivation of expressions for the gravitational potential of

229   the topography and its isostatic compensation derived from Newton's law of gravitation. The

230   potential of the compensation has invariably been derived assuming Airy isostasy (e.g. Kaula

231   1967; Lachapelle 1976; Rapp 1982, 1989; Rummel *et al.* 1988; Kuhn 2003), though some

232   researchers have considered the effects of flexural rigidity in their models, both indirectly

233   (e.g. Sünkel 1985; Rummel *et al.* 1988; Abd-Elmotaal 1993; Kuhn 2003), and directly (e.g.

234   Watts & Moore 2017).

235

236   In their formulations, Sünkel (1985) and Rummel *et al.* (1988) use a Gaussian smoothing

237   operator to generalise the Airy compensation model to the regional (Vening Meinesz) model,

238   rather than employing an expression derived from physical principles, such as ξ in eq. (7),

239   though Rummel *et al.* (1988) do note the correspondence. Both studies estimate the

240   parameters of the Gaussian function using least squares minimization of the resultant isostatic

241   anomaly. Abd-Elmotaal (1993) and Kuhn (2003) both compute Vening Meinesz isostatic

242   anomalies using space domain solutions of the plate bending equations, following Brotchie &

243   Silvester (1969). It should be noted, however, that if computation areas are small enough so

244　　that Earth curvature effects are minimal, then spherical solutions of the plate bending

245　　equations should give identical results to planar solutions.

246

247　　A technique that has reappeared in the literature in the past decade is a development of a

248　　concept originally proposed by Vening Meinesz (1931) that Moho depths can be obtained

249　　from the Bouguer anomaly. This so-called "inverse problem of isostasy" was built upon by

250　　Moritz (1990) and later Sjöberg (2009) who dubbed it the VMM (Vening Meinesz-Moritz)

251　　inverse problem. As noted by Moritz (1990) the method is the spherical equivalent of

252　　Parker's (1972) planar method to determine the gravity field due to an undulating, subsurface

253　　density contrast – or rather its inverse. However, despite the name 'Vening Meinesz'

254　　implying regional isostatic compensation, the VMM (and Parker) methods make no

255　　assumptions about, or even invoke, a particular method of isostatic compensation. Thus the

256　　method, while useful, cannot be said to describe any state of isostasy because it simply

257　　assumes that the entire Bouguer anomaly is due solely to undulations of the Moho density

258　　contrast; the surface topography – essential to any isostatic model – does not feature in the

259　　formulation. Recently, Eshagh (2016) showed that the VMM method is a generalisation of

260　　the Airy-Heiskanen model, while Eshagh (2018) has attempted a reconciliation of the VMM

261　　method with more established methods of modelling flexural isostasy.

262

263　**3 TESTS ON SYNTHETIC ISOSTATIC ANOMALIES**

264　**3.1 Generation of the synthetic data**

265　In order to test how well the isostatic anomaly can be retrieved from real data, one can use

266　synthetic plate models with known parameters. Since the work of Macario *et al.* (1995),

267　synthetic testing of T_e-estimation methods is now well-established (see Kirby (2014) for a

268　summary). Initial surface and subsurface loads are represented by random, fractal surfaces

269   (Saupe 1988; Macario *et al.* 1995), and for uniform-T_e plates the post-loading Bouguer

270   anomaly and surface topography are found by solving the flexural equation with the Fourier

271   transform (e.g. Kirby 2014). Unless otherwise noted, in all experiments here the synthetic

272   models were generated using a single-layer crust of density 2800 kg m^{-3} and thickness 35 km,

273   overlying a mantle of density 3300 kg m^{-3} (Table 1). When invoked, the initial subsurface

274   load was emplaced at the base of the crust, 35 km depth.

275

276   Synthetic Bouguer anomaly and topography pairs were generated from combined loading on

277   plates with T_e and f values described in Sections 3.2 and 3.3, following Macario *et al.* (1995).

278   Since the quantity f is unbounded $[0, \infty)$ results are presented in terms of F which is bounded

279    $[0, 1]$ and is the fraction of the initial subsurface load to the total initial load amplitude:

280    $$F = \frac{f}{1+f} \qquad f = \frac{F}{1-F} \tag{10}$$

281   Surface-only initial loading is given by $f = 0$ and $F = 0$ at all wavenumbers; subsurface-only

282   initial loading is given by $f = \infty$ and $F = 1$ at all wavenumbers; equal combined loading is

283   given by $f = 1$ and $F = 0.5$ at all wavenumbers.

284

285   Once the Bouguer anomaly and topography pairs were generated, the compensation attraction

286   (δg_C) was computed from eq. (3) by multiplying the final topography Fourier transform (H)

287   by a theoretical Bouguer admittance function (Q_{th}), and inverse Fourier transforming, thus

288    $$\delta g_C(\mathbf{x}) = \mathbf{F}^{-1}\left[Q_{th}(k)H(\mathbf{k})\right] \tag{11}$$

289   where Q_{th} could be any of the analytic functions given by eqs (5), (7), (8) or (9). Note that

290   isotropic admittances were used, as functions of $k = |\mathbf{k}|$. The parameters of the admittance

291   functions (crust and mantle densities and crustal thickness) were identical to those of the

292   synthetic model (unless otherwise specified). An isostatic anomaly (Δg_I) was then recovered

293   by subtracting the compensation attraction from the synthetic model Bouguer anomaly as in

294   eq. (4). Hence, because there are no non-flexural signals in the synthetic Bouguer anomaly

295   and topography, if the correct compensation model (admittance function) is chosen then the

296   compensation attraction should exactly reproduce the Bouguer anomaly, yielding uniformly

297   zero isostatic anomalies.

298

299   **3.2 Tests of varying T_e and F**

300   Here, 10,100 synthetic Bouguer anomaly and topography pairs were generated from

301   combined loading on plates with T_e ranging from 0 to 100 km, in steps of 1 km (101 values),

302   and F ranging from 0 to 0.99, in steps of 0.01 (100 values).

303

304   *3.2.1 Assuming Airy isostasy*

305   In the first test ('test A'), the compensation attraction was computed for each of the 10,100

306   synthetic models from its topography using the Airy isostatic admittance function, i.e.

307     $\delta g_C = \mathbf{F}^{-1}\left[Q_A H\right]$ with Q_A given by eq. (5). The densities and compensation depth, z_m, were

308   set equal to the synthetic model values, given above. The isostatic anomaly corresponding to

309   a synthetic model (F, T_e) value was then computed using eq. (4), and its standard deviation

310   (σ_{IA}) determined. Rather than plotting the standard deviations directly, they were normalized

311   (to $\bar{\sigma}_{IA}$) by the Bouguer anomaly standard deviation at the model (F, T_e) value and then

312   plotted, shown in Fig. 1(a). This normalization was performed to place a proper perspective

313   on apparently large isostatic anomalies, which might not be large compared to the

314   corresponding Bouguer anomalies. Thus $\bar{\sigma}_{IA}$ is interpreted as the error in using the chosen

315   compensation model, in this case the Airy model, i.e. assuming $T_e = F = 0$, when the reality is

316   that T_e and F are not necessarily zero. As noted in the caption to Fig. 1, the maximum value

317   of $\bar{\sigma}_{IA}$ in Fig. 1(a) is 2.14, occurring when the model T_e is 100 km and there is no subsurface

318   load ($F = 0$). An alternative way of phrasing this is that the total amplitude of the isostatic

319   anomaly at these T_e and F values is 214 per cent that of the corresponding Bouguer anomaly.

320

321   Fig. 1(a) shows that when the synthetic models were generated with $T_e = 0$ km (for any value

322   of the initial subsurface load fraction F), the isostatic anomalies were uniformly zero,

323   confirming that the compensation attraction perfectly reproduces the Bouguer anomaly, and

324   that the method used to recover isostatic anomalies performs adequately. Recall from Section

325   2.1 that when $T_e = 0$ km, surface and subsurface loading are indistinguishable in their results,

326   explaining why the locus of zero standard deviation extends from $F = 0$ to $F = 1$.

327

328   Fig. 1(a) suggests that, when the increased power of the Bouguer anomalies is accounted for,

329   the Airy model is appropriate for many combinations of the plate's actual T_e and F values (

330    $\bar{\sigma}_{IA} < 10$ per cent, for example). But both of these interpretations are misleading, as Fig. 2(a)

331   shows, which plots the power spectra of the Bouguer and isostatic anomalies. Fig. 2(a)

332   demonstrates that in regions of the (F, T_e)-space where $\bar{\sigma}_{IA}$ is low but $T_e > 0$ and F is high

333   (e.g. $T_e = 25$ km, $F = 0.75$), the low values of $\bar{\sigma}_{IA}$ are caused by low relative isostatic

334   anomaly power at mid-to-long wavelengths only, and at mid-to-short wavelengths, the

335   Bouguer and isostatic anomalies actually have equal power. That is, the low values of $\bar{\sigma}_{IA}$ in

336   Fig. 1(a) are biased by the large difference in long wavelength power. And because the

337   Earth's gravity and topography naturally have red power spectra (high power at long

338   wavelengths, low power at short), the high isostatic anomaly power at short wavelengths,

339   relative to the Bouguer anomaly, contributes much less to the overall whole-spectrum power

340   difference, by several orders of magnitude. Thus, minimization of the isostatic anomaly

341 standard deviation alone (as done by several studies, noted in Section 1) will give misleading

342 conclusions as to the actual state of compensation/support, even when the Bouguer anomaly

343 standard deviation is accounted for. Instead, the spectra of Bouguer and isostatic anomalies

344 over a region should be compared (and one should use Bouguer and not free air anomalies in

345 the comparison since the gravity effect of the topography has been removed when generating

346 both Bouguer and isostatic anomalies – making them compatible – but not removed from free

347 air anomalies). And it is only when the isostatic anomaly power spectrum is much less than

348 that of the Bouguer anomaly at all wavelengths that the conclusion should be made that the

349 assumed compensation mechanism is a faithful representation of the actual compensation

350 mechanism. Estimates of the isostatic parameters (e.g. T_e) needed to choose or refine the

351 compensation model can be readily obtained from spectral methods (e.g. Kirby 2014).

352

353 Fig. 2(a) shows that when subsurface loading dominates ($F > 0.5$) the Airy isostatic

354 anomalies have equal power to the Bouguer anomalies at mid-to-short wavelengths, even for

355 relatively low-rigidity plates ($T_e \leq 25$ km). Furthermore, their spectral content becomes

356 higher-power and longer-wavelength as T_e increases. If the plate is strong and F close to 1,

357 the initial subsurface loads will not cause a surface (topographic) deflection and their

358 presence will not be measurable in the topography Fourier transform, H; therefore, the

359 compensation attraction, $\mathbf{F}^{-1}[Q_A H]$, will be small, reflecting only any low-amplitude initial

360 surface loads that may be present. Since the Bouguer anomaly will be large, due to the large

361 subsurface loads, the isostatic anomaly will also be large.

362

363 Fig. 2(a) also shows that, when surface loading dominates ($F < 0.5$), the Airy isostatic

364 anomalies can have greater power than the Bouguer anomalies at the shorter wavelengths, a

365 phenomenon that becomes more pronounced when T_e is large and subsurface loading is

366 reduced. In this case, the surface loads are supported by the plate's rigidity, so H has higher

367 power than it would on a weak plate, leading to an excess of power in the compensation

368 attraction by virtue of $\mathbf{F}^{-1}[Q_A H]$, which propagates into the isostatic anomalies.

369

370 *3.2.2 Assuming surface loading*

371 In the second test ('test B'), the compensation attraction was computed for each of the 10,100

372 synthetic models from its topography using the surface-loading admittance function, i.e.

373 $\Delta g_C = \mathbf{F}^{-1}[Q_T H]$ with Q_T given by eq. (7) using the T_e value of the synthetic model. The

374 densities and compensation depth, z_m, were set equal to the synthetic model values, given

375 above. The isostatic anomaly was then computed using eq. (4), and its normalized standard

376 deviation determined and plotted in Fig. 1(b) at the location given by the model (F, T_e) value.

377 The normalized standard deviation is interpreted here as the error in assuming only initial

378 surface loading; i.e., using the correct T_e, but assuming $F = 0$, when the reality is that F is not

379 necessarily zero. As noted in the caption to Fig. 1, the maximum value of $\bar{\sigma}_{IA}$ in Fig. 1(b) is

380 0.36, occurring when the model T_e is 100 km and there is almost no surface load ($F = 0.99$).

381 So whereas the assumption of Airy isostasy gave rise to isostatic anomalies having

382 amplitudes at 214 per cent of the Bouguer anomaly, when surface-only loading is assumed

383 the isostatic anomalies are much smaller, reaching only 36 per cent of the Bouguer anomaly

384 amplitude.

385

386 First, Fig. 1(b) shows that when the synthetic models were generated with $F = 0$ (for any

387 value of T_e), the isostatic anomalies were uniformly zero, showing that the compensation

388 attraction perfectly reproduces the Bouguer anomaly, and that the method used to recover

389 isostatic anomalies performs adequately as long as T_e is known. Zero isostatic anomalies also

390   occur when $T_e = 0$ km, for any value of F because surface and subsurface loading are

391   indistinguishable in their results, as explained before.

392

393   As discussed above, the power spectra reveal more information than the standard deviation

394   plots. The power spectra for test B are shown in Fig. 2(b). When initial loading is more

395   surface than subsurface ($F < 0.5$), a comparison of Figs 2(a) and 2(b) shows that the

396   assumption of surface loading with a knowledge of the actual T_e generally results in lower-

397   power isostatic anomalies than the assumption of Airy isostasy, especially in the mid-to-short

398   wavelengths. Not shown in Fig. 2(b) are the isostatic anomaly spectra for $F = 0$, which are

399   uniformly zero at all wavelengths, as expected.

400

401   In contrast, when initial loading is more subsurface than surface ($F > 0.5$), the assumption of

402   surface loading results in higher-power long wavelength isostatic anomalies compared to

403   Airy isostasy, by as much as two orders of magnitude. In conclusion, knowledge of T_e will

404   not necessarily provide an improved compensation model.

405

406   *3.2.3 Assuming combined loading*

407   In the third test ('test C'), the compensation attraction was computed for each of the 10,100

408   synthetic models from its topography using the combined-loading admittance function, i.e.

409     $\delta g_C = \mathbf{F}^{-1}\left[Q_{TB}H\right]$ with Q_{TB} given by eq. (9) using the T_e and F values of the synthetic model.

410   The densities and compensation depth, z_m, were set equal to the synthetic model values, given

411   above. The isostatic anomaly was then computed using eq. (4), and its normalized standard

412   deviation determined and plotted in Fig. 1(c) at the location given by the model (F, T_e) value.

413   The normalized standard deviation is interpreted here as the error in assuming combined

414   loading; i.e., using the correct T_e and F. In other words, there should be no error.

415

416   In tests A and B the non-zero isostatic anomalies were explained as arising from a lack of

417   knowledge about the actual compensation mechanisms; incorrectly assuming Airy isostasy in

418   test A, and surface-loading in test B, when the reality was combined loading of a rigid plate.

419   However, in test C, since the model T_e, F, z_m and density values are known and used to

420   compute the compensation attraction, it would be reasonable to expect that the correct

421   compensation model (the correct theoretical admittance) had been used, giving uniformly

422   zero $\overline{\sigma}_{IA}$ over Fig. 1(c). While this is not seen, the $\overline{\sigma}_{IA}$ values are somewhat smaller for test

423   C than test B [with a maximum value of $\overline{\sigma}_{IA}$ in Fig. 1(c) of 30 per cent at $T_e = 100$ km, $F =$

424   0.3], suggesting that some knowledge of subsurface loading is an improvement over the

425   assumption of surface loading only, especially for almost complete surface-only ($F < 0.05$)

426   and subsurface-only ($F > 0.95$) initial loading. Nevertheless, when the power spectra are

427   analysed (Fig. 2c), the short-wavelength isostatic anomaly power is considerable for $T_e \geq 10$

428   km and $F \geq 0.25$. Compared to the results from Airy isostasy (test A, Fig. 2a), the long-

429   wavelength isostatic anomaly power from combined loading is several orders of magnitude

430   lower when F is low or high, but not with intermediate values ($0.25 \leq F \leq 0.75$) when the

431   power is similar at all wavelengths. Importantly, the power is not uniformly zero, when it

432   should be.

433

434   Evidently, further analysis is required, and this analysis should focus upon the role of

435   subsurface loading, since in the tests conducted so far the isostatic anomaly power increases

436   with increasing subsurface load amplitude, for a given T_e. The investigation should also focus

437   on the admittance, since, as discussed in Section 3.2.1, the lack of subsurface load signal in

438   the surface topography transform, H, for high T_e leads to inaccurate compensation attractions

439   by virtue of $\mathbf{F}^{-1}[Q_{th}H]$. Indeed, a full explanation can only be made by studying the complex

440   nature of the admittance.

441

442   *3.2.4 Complex admittance*

443   When used in flexural studies, the admittance is assumed to be real-valued. However, in

444   general – when many processes are operating – it will be complex (e.g. Forsyth 1985; Kirby

445   & Swain 2009; Kirby 2014). This can be seen in the formula to estimate the admittance. The

446   observed Bouguer admittance, Q_{obs}, is estimated from observed data (real or synthetic) via a

447   formula of the type

448
$$Q_{obs}(\mathbf{k}) = \frac{\langle G(\mathbf{k})H(\mathbf{k})^* \rangle}{\langle H(\mathbf{k})H(\mathbf{k})^* \rangle} \qquad (12)$$

449   (e.g. Forsyth 1985) where G is the Fourier transform of the Bouguer anomaly, H is the

450   Fourier transform of the topography, the asterisk denotes complex conjugation, and the angle

451   brackets indicate some averaging process which can give an isotropic (1-D) $Q(k)$, or an

452   anisotropic (2-D) $Q(\mathbf{k})$ (see Kirby (2014) for a summary). In general, the numerator of eq.

453   (12) will be complex, as shown ahead.

454

455   Consider two noise-free, independent processes, for instance surface ($_T$) and subsurface ($_B$)

456   loading. Let $G_T = Q_T H_T$, and $G_B = Q_B H_B$, in the Fourier domain, where the Qs are real-

457   valued, given by eqs (7) and (8), and all variables are functions of wavevector $\mathbf{k}$. Then the

458   final gravity will be $G = G_T + G_B$, and the final topography will be $H = H_T + H_B$ (Forsyth

459   1985). Substituting these expressions in eq. (12), the combined admittance is

460
$$Q_{TB}' = \frac{\langle (Q_T H_T + Q_B H_B)(H_T + H_B)^* \rangle}{\langle (H_T + H_B)(H_T + H_B)^* \rangle} \qquad (13)$$

461 Letting $H_T = |H_T|e^{i\alpha_T}$ and $H_B = |H_B|e^{i\alpha_B}$, where the phases α are functions of wavenumber,

462 it can be shown that the combined admittance is indeed complex:

463 $$Q_{TB}' = \frac{\left\langle Q_T|H_T|^2 + Q_B|H_B|^2 + (Q_T + Q_B)|H_T||H_B|\cos\theta \right\rangle + i\left\langle (Q_T - Q_B)|H_T||H_B|\sin\theta \right\rangle}{\left\langle |H_T|^2 + |H_B|^2 + 2|H_T||H_B|\cos\theta \right\rangle} \qquad (14)$$

464 where the phase difference $\theta = \alpha_T - \alpha_B$ is also wavenumber-dependent.

465

466 Eq. (14) can be turned into a theoretical analytic equation for admittance in the following

467 manner. Write eq. (14) as

468 $$Q_{TB}' = \frac{Q_1' + Q_2'}{Q_3'} \qquad (15)$$

469 and treat the real part of the numerator (Q_1') initially:

470 $$Q_1' = \left\langle Q_T|H_T|^2 + Q_B|H_B|^2 + (Q_T + Q_B)|H_T||H_B|\cos\theta \right\rangle \qquad (16)$$

471 In his paper, Forsyth (1985) introduced the initial loading ratio, f, as the ratio of the weight of

472 the applied load at the Moho to that of the applied load on the surface, and expressed it as

473 $$f(\mathbf{k})r|H_T(\mathbf{k})| = \xi|H_B(\mathbf{k})| \qquad (17)$$

474 where ξ is defined in eq. (7), and r in Section 2.1. Thus, using eq. (17), eq. (16) becomes

475 $$Q_1' = \left\langle Q_T|H_T|^2 + Q_B f^2 r^2 \xi^{-2}|H_T|^2 + (Q_T + Q_B)fr\xi^{-1}|H_T|^2\cos\theta \right\rangle \qquad (18)$$

476 The averaging is typically performed over the 360° of an annulus in the wavevector, $\mathbf{k}$, space,

477 with many annuli spanning the space, yielding an isotropic quantity as a function of

478 wavenumber modulus, $k = |\mathbf{k}|$. The wavenumber-dependent functions ξ, Q_T and Q_B are

479 smooth and slowly varying analytic functions, so if the annuli are very narrow, spanning a

480 very small range of k, they can be treated as constants and taken out of the averaging. Thus

481 eq. (18) can be written as

482 $$Q_1' = Q_T \left\langle \left| H_T \right|^2 \right\rangle + Q_B r^2 \xi^{-2} \left\langle f^2 \left| H_T \right|^2 \right\rangle + \left(Q_T + Q_B \right) r \xi^{-1} \left\langle f \left| H_T \right|^2 \cos\theta \right\rangle \qquad (19)$$

483 Taking the loading ratio, $f(\mathbf{k})$, and phase difference, $\theta(\mathbf{k})$, out of the averaging procedure is

484 perhaps harder to justify since they are dependent on the data and most likely will not be

485 smooth and slowly varying but instead potentially highly variable functions of wavevector $\mathbf{k}$.

486 Additionally, the phase difference contains the phase information of H_T and H_B. Therefore in

487 order to obtain an all-purpose analytic expression for Q_{TB}', one that is data-independent akin

488 to eqs (7) – (9), one must make three assumptions. First, Kirby & Swain (2009) reasoned that

489 if the amplitudes and phases of the data are independent then one can write

490 $\left\langle f(\mathbf{k}) \left| H_T(\mathbf{k}) \right|^2 \cos\theta(\mathbf{k}) \right\rangle \approx \left\langle f(\mathbf{k}) \left| H_T(\mathbf{k}) \right|^2 \right\rangle \left\langle \cos\theta(\mathbf{k}) \right\rangle$. Their second assumption was that if

491 the amplitudes of the surface and subsurface processes are independent then $\left\langle f(\mathbf{k}) \left| H_T(\mathbf{k}) \right|^2 \right\rangle$

492 $\approx f(k) \left\langle \left| H_T(\mathbf{k}) \right|^2 \right\rangle$. Third, they assumed that if the phase difference is independent of

493 azimuth, then $\left\langle \cos\theta(\mathbf{k}) \right\rangle \approx \cos\theta(k)$. Hence, with these assumptions, eq. (19) becomes

494 $$Q_1' = \left[Q_T + Q_B f^2 r^2 \xi^{-2} + \left(Q_T + Q_B \right) f r \xi^{-1} \cos\theta \right] \left\langle \left| H_T \right|^2 \right\rangle \qquad (20)$$

495

496 Applying the same treatment to the imaginary part of the numerator of eq. (14) and its

497 denominator gives

498 $$Q_2' = i \left(Q_T - Q_B \right) f r \xi^{-1} \sin\theta \left\langle \left| H_T \right|^2 \right\rangle \qquad (21)$$

499 and

500 $$Q_3' = \left[1 + f^2 r^2 \xi^{-2} + 2 f r \xi^{-1} \cos\theta \right] \left\langle \left| H_T \right|^2 \right\rangle \qquad (22)$$

501

502 A final observation made by Kirby & Swain (2009), made on synthetic data, was that

503 correlated initial loads had the property $\langle \cos\theta \rangle \approx 1$, while randomly correlated loads had

504 $\langle \cos\theta \rangle \approx 0$, implying that the correlated loading regime is characterised by $\theta = 0°$ and the

505 randomly-correlated regime by $\theta = 90°$ (see also Wieczorek (2007)). Since in this study the

506 synthetic loads are all randomly correlated we can use $\cos\theta = 0$ and $\sin\theta = 1$ in eqs (20) –

507 (22), which makes eq. (15) become

508
$$Q_{TB}' = \frac{\left(Q_T + Q_B f^2 r^2 \xi^{-2}\right)\left\langle |H_T|^2 \right\rangle + i\left(Q_T - Q_B\right) fr\xi^{-1}\left\langle |H_T|^2 \right\rangle}{\left(1 + f^2 r^2 \xi^{-2}\right)\left\langle |H_T|^2 \right\rangle}$$
(23)

509 Cancelling the $\left\langle |H_T|^2 \right\rangle$ terms, and using eqs (7) and (8), the analytic expression can be

510 written as

511
$$Q_{TB}'(k) = -2\pi \mathcal{G} \Delta\rho_0 e^{-kz}\left(\frac{\xi + \phi f^2 r^2 \; + \; ifr\left(1 - \phi\xi\right)}{\xi^2 + f^2 r^2} \right)$$
(24)

512 Note how the real part of eq. (24) is identical to eq. (9), the (real) combined-loading

513 admittance.

514

515 The (complex) 2-D observed admittance of the synthetic models was computed in

516 wavenumber space using eq. (12) and using Slepian multitapers (see Fig. 3 caption). Rather

517 than plotting the 2-D observed admittance estimates as a function of $\mathbf{k} = (k_x, k_y)$, they were

518 plotted (without averaging around annuli) on 1-D graphs as functions of their radial

519 wavenumber $k = |\mathbf{k}|$ as green dots in Fig. 3. The blue curves in Fig. 3 show the real and

520 imaginary theoretical admittance functions from eq. (24).

521

522 Figs 3(a) and (b) show that when the synthetic Bouguer anomaly and topography were

523 generated from a plate with $T_e = 0$ km (Airy isostasy, implying $F = 0$) the real and imaginary

524   observed admittance estimates agreed very well with the theoretical curves. When they were

525   generated from surface-loading only ($F = 0$) on a plate of $T_e = 40$ km, there was also good

526   agreement (Figs 3c and d). Note how the observed imaginary parts in Figs 3(b) and (d) are

527   almost uniformly zero at all wavelengths, agreeing with the theoretical predictions of eq. (24)

528   when $f = F = 0$.

529

530   When the synthetic Bouguer anomaly and topography were generated from combined loading

531   ($F = 0.5$) of a plate with $T_e = 40$ km, the real observed admittance estimates show a certain

532   degree of scatter about the theoretical curve (Fig. 3e), particularly at medium to short

533   wavelengths, which is expected and arises from random correlations between the two

534   synthetic loads (Kirby & Swain 2008). In contrast to the Airy and surface loading models, the

535   observed admittance in the combined loading case gains a non-zero imaginary part (Fig. 3f),

536   in agreement with eqs (14) and (24) because there are now two independent processes in

537   action. But it can be seen that the imaginary observed admittance estimates in Fig. 3(f) do not

538   follow the imaginary theoretical admittance curve; they cluster about the zero-admittance

539   axis, rather than the theoretical imaginary curve. [Interestingly, there are no estimates that lie

540   outside the curve (and its negative reflection about the axis), so it could be said that the

541   theoretical curve provides an envelope within which all observed imaginary admittance

542   estimates fall.]

543

544   This mismatch between the observed and theoretical imaginary admittance provides the

545   answer to the problem raised above: why is the isostatic anomaly for combined loading non-

546   zero (Fig. 1c), when the loading model is known exactly? First note that with any type of

547   noise-free synthetic flexure model, in order to retrieve zero isostatic anomalies the

548   compensation attraction must be perfectly recovered from a formula of the type

549     $\delta g_C = \mathbf{F}^{-1}[Q_{th}H]$, and for this the admittance Q needs to be an accurate representation of the

550   actual synthetic model plate filter, where, given initial loads the plate filter produces a gravity

551   anomaly and topography. Whether this filter is manifested as flexural equations or as

552   admittances is unimportant. Indeed, if the observed (complex) admittance, Q_{obs}, was

553   computed from the synthetic Bouguer anomaly and topography through eq. (12) and then a

554   compensation attraction retrieved via $\delta g_C = \mathbf{F}^{-1}[Q_{obs}H]$, the synthetic Bouguer anomaly and

555   retrieved compensation attraction would be almost identical (but not exactly due to multitaper

556   averaging when computing the admittance). This would apply to real-Earth data too, except

557   here Q_{obs} would contain much more than just isostatic information.

558

559   Consequently, in the surface-only loading model the real theoretical admittance curves are a

560   very good fit to the real observed admittance estimates (Fig. 3c), so that when the theoretical

561   admittance function, eq. (7), is used with the topography Fourier transform in eq. (11), or

562     $\delta g_C = \mathbf{F}^{-1}[Q_T H]$, the retrieved compensation attraction exactly reproduces the actual

563   Bouguer anomaly. That is, performing $\mathbf{F}^{-1}[Q_T H]$ with a theoretical admittance gives almost

564   the same results as performing $\mathbf{F}^{-1}[Q_{obs}H]$ with an observed admittance; both yield a

565   compensation attraction that exactly matches the Bouguer anomaly (for these noise-free,

566   surface-loading synthetic models). The same is true for the Airy isostatic case.

567

568   In the combined-loading models the compensation attraction is also obtained using a real-

569   valued theoretical analytic admittance, $\delta g_C = \mathbf{F}^{-1}[Q_{TB}H]$ with Q_{TB} given by eq. (9). But even

570   though Q_{TB} is a fair fit to the real, observed admittance (Fig. 3e), use of a real-valued analytic

571   admittance will always yield antiphase (180°) compensation attraction and topography when

572   in fact the combined model synthetic Bouguer anomaly and topography actually have random

24

573 phase due to the independence of the initial surface and subsurface loads. This means that the

574 difference $\Delta g_B - \delta g_C$ will not account for the out-of-phase harmonics between Δg_B and h, and

575 will be non-zero. Since $\Delta g_B - \delta g_C$ is interpreted as the isostatic anomaly (eq. (1)), it appears

576 that there exists a non-zero isostatic anomaly even in this noise-free example. The conclusion

577 is that the compensation model has failed, even if T_e, F, densities and depths have actually

578 been estimated accurately.

579

580 And unfortunately the situation cannot be remedied by use of a complex analytic admittance,

581 which would at least generate out-of-phase gravity and topography; for example, using $Q_{TB}{}'$

582 from eq. (24) to generate the compensation attraction from $\delta g_C = \mathbf{F}^{-1}\left[Q_{TB}{}' H \right]$. While the real

583 part of $Q_{TB}{}'$ is a fair fit to the real, observed admittance (Fig. 3e), its imaginary part is

584 definitely not (Fig. 3f), so $\mathbf{F}^{-1}\left[Q_{TB}{}' H \right]$ will not yield anything remotely resembling the

585 compensation attraction. Therefore, while useful in providing a theoretical understanding of

586 phase relationships between gravity and topography, complex analytic admittance formulae

587 such as eq. (24) have little practical value. This is most likely due to the assumptions made

588 regarding the phase difference θ when deriving eq. (24).

589

590 In summary, if both surface and subsurface loading are present, then the correct

591 compensation and isostatic anomalies cannot be estimated using spectral methods. Complex

592 analytic admittance functions do not faithfully represent the imaginary admittance, while real

593 analytic admittance functions cannot correctly predict the phase difference between gravity

594 and topography.

595

3.3 Tests of varying compensation depth

This experiment sought to ascertain the error in estimating compensation depth, when an Airy isostatic model is used to interpret gravity and topography data generated from a plate with T_e > 0 km. As described in Section 3.2, 10,100 synthetic Bouguer anomaly and topography pairs were generated from combined loading on plates with T_e ranging from 0 to 100 km, in steps of 1 km (101 values), and F ranging from 0 to 0.99, in steps of 0.01 (100 values). Lithospheric parameters were set as: crust density 2800 kg m^{-3}, crust thickness (and compensation depth) 35 km, mantle density 3300 kg m^{-3}, as usual. The compensation attraction was then recovered from the topography using the Airy admittance function, eq. (5) , 196 times, using depth to compensation values (z_m) ranging from 5 to 200 km, in steps of 1 km. From each of the 1,979,600 (= 101 × 100 × 196) compensation attractions the corresponding isostatic anomaly was computed using eq. (4), and its normalized standard deviation ($\bar{\sigma}_{IA}$) calculated (an example for F = 0 is shown in Fig. 4a). For each model with a certain (F, T_e) value, the value of z_m that gave the smallest $\bar{\sigma}_{IA}$ was determined, and plotted in Fig. 4(b).

Both plots in Fig. 4 show how compensation depth can be overestimated if an Airy model is assumed, when loading is surface-only. For example, consider a region of the Earth where the actual, but unknown, T_e is 40 km, and one wishes to find the compensation depth when erroneously assuming that T_e = 0 km. If one used a method to find the compensation depth such as that presented here, i.e. by finding that compensation depth over a range of values that minimized the isostatic anomaly standard deviation, one would retrieve $z_m \approx 110$ km from Figs 4(a) and (b), a value greater than its true value by 75 km. For combined-loading scenarios (F > 0), Fig. 4(a) no longer applies and one must turn to Fig. 4(b). Now, if the

620   actual T_e were 40 km but the internal load fraction $F = 0.5$, then the estimated compensation

621   depth would be approximately 50 km.

622

623   Fig. 4(b) shows that the largest overestimates of the actual compensation depth occur when

624   the initial loading is predominantly at the surface ($F < 0.5$), and then when T_e is high.

625   Furthermore, large underestimates of compensation depth occur when there exist significant

626   subsurface loads ($F > 0.8$) in a plate of high T_e. Indeed, compensation depth is only recovered

627   accurately in a very narrow range of (F, T_e) values, $T_e < 5$ km, or $0.65 < F < 0.7$,

628   approximately, as shown by the red contours in Fig. 4(b).

629

630   **4 DISCUSSION**

631   **4.1 Subsurface loading**

632   Studies have shown that that subsurface loading exists in many regions worldwide, and that it

633   plays a key role in flexure and in the compensation of surface loads (e.g. Karner & Watts

634   1983). However, it has been shown in Section 3.2.4 that combined surface and subsurface

635   loading cannot be realistically accounted for in the determination of isostatic anomalies. This

636   is because the admittance, when multiplied by the observed surface topography, does not

637   accurately model the compensation at the surface of subsurface loads generated during

638   combined loading and flexure of a plate of $T_e > 0$ km. Since subsurface loading, and its effect

639   upon the surface topography and gravity field, is part of the flexural-isostatic process, the

640   question of whether an isostatic anomaly is meaningful must be raised.

641

642   The detrimental effect of subsurface loads upon isostatic anomaly estimation is not unknown.

643   Such loads can be emplaced or generated during many tectonic events such as the obduction

644   of oceanic crust, the development of accretionary wedges and the mobilization of thrust

27

645 sheets and nappes during continental convergence, emplacement of subsurface plutons during

646 volcanic activity, intra-crustal thrusts, and dense downgoing slabs (e.g. Karner & Watts 1983;

647 Forsyth 1985; Jordan & Watts 2005). They may be shallow, such as crustal blocks of

648 different compositions, sedimentary basins, or igneous intrusions, or deep, such as density

649 anomalies due to crustal underplating, lithospheric thermal anomalies or deeper

650 compositional variations (Zuber *et al.* 1989). Most importantly, they are often expressed in

651 the Bouguer anomaly but not in the topography, leading to incorrect Airy isostatic anomalies

652 which are derived under the assumption that the topography is the only load acting on the

653 lithosphere (e.g. Watts & Talwani 1974; McNutt 1980; Karner & Watts 1983; Forsyth 1985).

654 For example, in their study of isostasy at orogenic belts, Karner & Watts (1983) showed that

655 the maximum crustal thickness in the Alps does not occur under the highest elevations as

656 Airy isostasy would predict, but rather under the large subsurface loads that characterise the

657 Ivrea zone. The rigidity of the lithosphere here prevents hydrostatic adjustment of the

658 subsurface density anomalies, but isostatic balance is still maintained.

659

660 The difficulty, if not impossibility, of accounting for subsurface loads when estimating

661 isostatic anomalies using transfer function (admittance) methods has been acknowledged

662 qualitatively by several authors (e.g. McNutt 1980; Ussami *et al.* 1993; Watts *et al.* 1995;

663 Harmon *et al.* 2006). This study has quantified and confirmed that. However, subsurface

664 loads can be included in an isostatic anomaly if the computation of their gravity effect is

665 performed in the space domain, as Karner & Watts (1983) did. Space domain modelling is,

666 however, comparatively tedious compared with admittance methods in that it involves

667 forward modelling the subsurface density distributions, perhaps constrained by independent

668 (e.g. seismic) data, and adjusting T_e to match the observed gravity field.

669

670   One possible approach would be to acknowledge but ignore subsurface loads, and use

671   surface-loading models only (e.g. Ussami *et al.* 1993; Watts & Moore 2017). And this might

672   be considered appropriate, given that the tests conducted in this paper have shown that the

673   real-valued combined loading admittance function, eq. (9), does not give correct isostatic

674   anomalies even when T_e, F and the compensation depth are known (test C, Fig. 1c).

675   However, the tests have also shown that the assumption of only surface loading when both

676   surface and subsurface loads are present can, in certain scenarios, yield larger isostatic

677   anomalies than when Airy isostasy is assumed (compare Figs 1a and b). It is worth noting

678   though that accurate knowledge of T_e, F and compensation depth (test C, Fig. 1c) does yield

679   smaller average isostatic anomalies than when these parameters are unknown, even though

680   the spatial distribution of computed isostatic anomalies may not reflect their actual

681   distribution.

682

683   **4.2 Coherence transition wavelength**

684   The assumption of local isostatic compensation underestimates the ability of the lithosphere

685   to mechanically support topographic loads, resulting in an overestimation of the depth to

686   compensation, as noted in Section 1, and demonstrated in Section 3.3. In many studies it is

687   often assumed that most surface topographic loads are isostatically compensated, or at least

688   that mechanically supported loads are of such a small wavelength as to be irrelevant to that

689   study's conclusions (e.g. Kaban *et al.* 1999, 2004). Often, this 'transition' wavelength (from

690   compensated to supported topography) is assumed to be uniform across the study area, with

691   an arbitrarily chosen value (e.g. Martinec 1994b; Kaban *et al.* 2004; Bagherbandi *et al.*

692   2015). Such assumptions are misplaced, however, as the transition wavelength depends upon

693   T_e and initial loading ratio (f).

694

695   One possible method to separate compensated from supported topography is to analyse the

696   wavenumber-domain coherence between Bouguer anomalies (G) and topography (H):

697    $$\gamma^2(k) \; = \; \frac{\left|\left\langle G(\mathbf{k})H(\mathbf{k})^* \right\rangle\right|^2}{\left\langle G(\mathbf{k})G(\mathbf{k})^* \right\rangle \left\langle H(\mathbf{k})H(\mathbf{k})^* \right\rangle}$$ (25)

698   (e.g. Forsyth 1985). The Bouguer coherence will have values close to zero at short

699   wavelengths because such small loads can be adequately supported by the mechanical

700   strength of the plate (Fig. 5): small surface loads retain a topographic signature but do not

701   generate a Bouguer anomaly because the compensating interface (e.g. the Moho) does not

702   flex; small subsurface loads generate a Bouguer anomaly but do not produce a surface

703   topography by flexure. At the other end of the spectrum, long wavelength loads cannot be

704   mechanically supported, and the loads (both surface and subsurface) are hydrostatically

705   compensated; the Bouguer coherence is hence unity. There is, then, a transition wavelength

706   (λ_T), at which the Bouguer anomaly and topography transition from being incoherent (with

707   wavelength $\lambda < \lambda_T$) to coherent ($\lambda > \lambda_T$), which can also be interpreted as the wavelength at

708   which the loads transition from being supported to compensated.

709

710   By way of example, Fig. 6(b) shows a map of the value of the predicted Bouguer coherence

711   transition wavelength over Europe and surrounding seas, where λ_T is taken to be the

712   wavelength at which the coherence has a value of 0.5. The predicted coherence was estimated

713   by application of the fan-wavelet adaptation of Forsyth's (1985) method (Kirby & Swain

714   2008) to EGM2008 gravity data (Pavlis et $al.$ 2012), rock-equivalent topography from the

715   Earth2014 model (Hirt & Rexer 2015), and the depths and densities of the CRUST1.0 model

716   (Laske et $al.$ 2013). The resulting T_e map (Fig. 6a) broadly agrees with the estimate obtained

717   by Pérez-Gussinyé & Watts (2005) using the multitaper method, and is not discussed here.

718

719   Note that the map in Fig. 6(b) shows the transition wavelength of both (post-flexure) surface

720   and subsurface loads, because the predicted coherence (and hence λ_T) is computed by

721   Forsyth's (1985) method that assumes that both types of load are present. Fig. 6(b) shows that

722   the transition wavelength from compensated to supported topography is highly variable, with

723   the weaker lithosphere of western and southern Europe much less able to mechanically

724   support large loads than the stronger eastern European and Asian lithosphere. The lithosphere

725   in western and southern Europe is able to support loads with wavelengths <400 km

726   approximately, while the stronger lithosphere to the east can adequately support loads with

727   wavelengths up to ~1200 km.

728

729   **4.3 Implications for dynamic topography studies**

730   Under the reasoning that the Earth's actual topography is the sum of isostatic and dynamic

731   components, models of isostatic compensation are frequently used to isolate dynamic

732   topography (e.g. Forte *et al.* 1993; Perry *et al.* 2002; Boschi *et al.* 2010; Komut *et al.* 2012;

733   Bagherbandi *et al.* 2015). To date Airy isostasy has been the model of choice. Assuming Airy

734   isostasy, the undulations of a seismically-determined Moho can be used to predict the

735   isostatic topography that the Moho undulations compensate, as shown below.

736

737   Consider an incompressible crust of uniform density ρ_c overlying an inviscid mantle of

738   greater uniform density ρ_m, and itself overlain by a fluid of lesser density ρ_f, either air or

739   water. An applied surface load also of density ρ_c then deflects the crust resulting in surface

740   topography $h(x)$ and Moho relief of $w(x)$. Under Airy isostatic compensation, the pressure

741   generated from displacement of the fluid by the surface topography must balance the pressure

742   generated by displacement of the mantle by the Moho, thus

743    $-\Delta\rho_0\, g\, h(x) \;=\; \Delta\rho_1\, g\, w(x)$ (26)

744   where g is the gravity acceleration, $\Delta\rho_0 = \rho_c - \rho_f$ and $\Delta\rho_1 = \rho_m - \rho_c$, giving

745     $$w(x) = -\frac{\Delta\rho_0}{\Delta\rho_1} h(x) \tag{27}$$

746   This is the Airy isostatic case, and it is instructive to work in the wavenumber domain by

747   taking the Fourier transform of eq. (27):

748     $$H(k) = -\frac{\Delta\rho_1}{\Delta\rho_0} W(k) \tag{28}$$

749   where capital letters indicate the function's Fourier transform. For example, 1 km of Moho

750   relief (W) compensates 0.179 km of subaerial surface topography (H), at any wavelength of

751   relief anomaly (using density values from Table 1).

752

753     $W(k)$ can be obtained from a seismic Moho model, then eq. (28) used to find $H(k)$ the derived

754   isostatic topography. Then, the difference between the actual, observed topography (from a

755   DEM for example) and the isostatic topography is interpreted as the dynamic topography.

756   Different authors have attributed different phenomena to explain the dynamic processes that

757   support the topography (e.g. Molnar *et al.* 2015), and it is not the purpose of this paper to

758   comment on those. However, as Molnar *et al.* (2015) point out, the error on most seismic

759   models of the Moho is at least 2 km and often more than 5 km, which by eq. (28) imparts an

760   error of at least 0.4 – 0.9 km on the isostatic, and thus dynamic, topography when derived in

761   this manner. This error, they say, is often greater than the estimate.

762

763   Another source of error arises from the omission of plate rigidity in solutions. The

764   contribution of flexural rigidity to such studies of dynamic topography can be estimated by

765   considering the amount of surface topography that is compensated or supported by a

766   specified Moho relief anomaly, in an extension of the Airy isostasy case discussed above.

767   When the plate possesses non-zero rigidity, two processes must be considered. The first

768   process, surface loading, asks 'when an initial surface load applied to a plate generates a

769   Moho relief anomaly of amplitude 1 km after flexure, what is the amplitude of the post-

770   flexural surface topography?' The solution is obtained in a similar manner to the Airy case,

771   above, but now the forces produced by the load are laterally distributed, and a fourth-order

772   derivative term representing the bending stress (e.g. Watts, 2001) must be introduced into eq.

773   (26):

774    $$-\Delta\rho_0\, g\, h_T(x) \;=\; \Delta\rho_1\, g\, w_T(x) \;+\; D\, \frac{\partial^4 w_T(x)}{\partial x^4} \tag{29}$$

775   Now using the subscript 'T' to denote surface loading, if D is spatially uniform, eq. (29) can

776   be solved by taking its Fourier transform:

777    $$-\Delta\rho_0\, g\, H_T(k) \;=\; \Delta\rho_1\, g\, W_T(k) \;+\; D\, k^4 W_T(k) \tag{30}$$

778   or:

779    $$H_T(k) \;=\; \frac{-\left(D\, k^4 + \Delta\rho_1 g\right)}{\Delta\rho_0 g}\, W_T(k) \tag{31}$$

780

781   Eq. (31) is plotted in Fig. 7(a) for several values of T_e, as a function of load wavelength ($\lambda' =$

782    $2\pi / k'$) where the load in this case is a delta function in the Fourier domain with value -1 km

783   at wavenumber k' and zero elsewhere (i.e. a sinusoid in the space domain), or $W_T(k) = -\delta(k -$

784    $k')$. Under Airy isostasy ($D = 0$), $W_T = -1$ km of Moho relief compensates $H_T = 0.179$ km of

785   surface topography, for any wavelength of Moho relief and surface topographic expression,

786   as noted above. However, as load wavelength decreases and/or T_e increases, it becomes

787   harder and harder to flex the plate sufficiently to produce 1 km of Moho relief. For example,

788   under initial surface loading, in order to compensate a 500 km-wavelength Moho relief

789   anomaly of amplitude -1 km on a plate with $T_e = 80$ km, a surface load of amplitude 4.319

33

790   km is required, or 4.14 km more than expected for Airy isostasy. Thus, if an Airy model is

791   used to separate the isostatic from dynamic topography, then the isostatic topography may be

792   underestimated and the dynamic topography therefore overestimated.

793

794   The second process, subsurface loading, asks 'when a subsurface load applied to a plate

795   generates a Moho relief anomaly of amplitude 1 km after flexure, what is the amplitude of the

796   post-flexural surface topography?' The subsurface loading analogue of eq. (30) is

797     $-\Delta\rho_1 g\, W_B(k) \;=\; \Delta\rho_0 g\, H_B(k) \;+\; D k^4 H_B(k)$ (32)

798   (e.g. Forsyth 1985) which becomes

799     $H_B(k) \;=\; \dfrac{-\Delta\rho_1 g}{D k^4 + \Delta\rho_0 g}\, W_B(k)$ (33)

800   Eq. (33) is plotted in Fig. 7(b) for several values of T_e, where $W_B(k) = -\delta(k - k')$. Under Airy

801   isostasy ($D = 0$), $W_B = -1$ km of Moho relief compensates $H_B = 0.179$ km of surface

802   topography, for any wavelength of Moho relief and surface topographic expression, as for the

803   surface loading case, above. However, as load wavelength decreases and/or T_e increases, the

804   surface topographic amplitude decreases to zero. For example, under initial subsurface

805   loading, a 500 km-wavelength Moho relief anomaly of amplitude 1 km on a plate with $T_e =$

806   80 km compensates a surface load of amplitude 0.035 km, or 0.144 km less than expected for

807   Airy isostasy. Thus, if an Airy model is used to separate the isostatic from dynamic

808   topography, then the isostatic topography may be overestimated and the dynamic topography

809   therefore underestimated. Note that it is difficult to combine the expressions for surface and

810   subsurface loading due to the likely phase difference between the two processes.

811

812   Hence it can be seen that determination of the isostatic topography, let alone dynamic

813   topography, is difficult. In addition to dealing with the error in Moho depth, one has to decide

814 whether surface or subsurface loading dominated the region, and be confident in that decision

815 because, as seen, the two can have very different results. While one could use the loading

816 ratio, f, provided by Forsyth's (1985) coherence method to estimate the relative amounts of

817 each loading type at different wavelengths, one would also have to recreate the initial loads in

818 order to ascertain the phase difference between them. Fortunately, recreating initial loads is

819 achievable via Forsyth's (1985) method (e.g. Bechtel *et al.* 1987), and Lowry *et al.* (2000)

820 have used such an approach when computing dynamic topography in the U.S. Cordillera.

821

822 Many studies write that they avoid the effect of flexural rigidity by low-pass frequency

823 filtering the data in order to operate in harmonics where loads are hydrostatically

824 compensated rather than mechanically supported (e.g. Forte *et al.* 1993; Perry *et al.* 2002;

825 Boschi *et al.* 2010; Komut *et al.* 2012; Bagherbandi *et al.* 2015). This supposition is correct

826 and can be seen in Fig. 7. For a given T_e value, the wavelength at which the $H_T(k)$ or $H_B(k)$

827 curve intersects the Airy ($T_e = 0$) line provides the minimum wavelength at which a dynamic

828 topography study will be free from the effects of flexural rigidity. For example, if $T_e = 80$ km

829 then low-pass filtering the observed topography and Moho relief with a cut-off of 2000 km

830 (spherical harmonic degree <20) will ensure that only Airy compensation signals are present

831 in the data. If T_e is lower, 10 km say, then the cut-off only need be 500 km (spherical

832 harmonic degree <80).

833

834 But as discussed in Section 4.2 the cut-off wavelength in the above-cited studies often seems

835 to be arbitrarily chosen, and sometimes is not chosen *per se* at all, but rather is implied by the

836 resolution of the Moho depth model (e.g. Perry *et al.* 2002; Boschi *et al.* 2010; Komut *et al.*

837 2012). Many studies overcompensate and select cut-off wavelengths far in excess of the

838 minimum needed (e.g. Forte *et al.* 1993; Bagherbandi *et al.* 2015). Three exceptions who

839   have taken elastic thickness into account when choosing cut-off wavelengths are Kaban *et al.*

840   (2004) and Braun *et al.* (2014), albeit differently to here, and Watts & Moore (2017) though

841   their study is of global average spectra.

842

843   **5 CONCLUSIONS**

844   It has been shown here that attempts to determine mechanisms of isostatic compensation of

845   surface topographic features, and thence isostatic gravity anomalies, are prone to failure for

846   several reasons. First, many attempts omit, by accident or design, flexural rigidity from

847   computations. As with any inversion method, omission of an important inversion parameter

848   will affect the values of those remaining parameters chosen for estimation, for example, the

849   depth to compensating interface. Experiments with synthetic models have shown that the

850   flexural rigidity, or its geometric analogue the effective elastic thickness, is indeed an

851   important parameter in isostatic compensation and its omission can affect isostatic anomaly

852   standard deviations by up to 214 per cent of the corresponding Bouguer anomaly standard

853   deviation, for the models considered here. To address these shortcomings, it is recommended

854   that (1) elastic thickness be included, if possible, in isostatic anomaly modelling, and (2) that

855   isostatic anomaly power spectra, rather than standard deviations, relative to the Bouguer

856   anomaly be analysed. The second recommendation is important because isostatic anomalies

857   may have a low standard deviation but still have high power at short wavelengths relative to

858   the Bouguer anomaly. This happens because of the redness of the Earth's gravity and

859   topography spectra: for example, a power difference of 10^3 between Bouguer and isostatic

860   anomalies at long wavelengths contributes much more to the whole-spectrum average power

861   than does a 10^3 power difference at short wavelengths.

862

863 Equally as important as elastic thickness is the role of subsurface loads. Such loads are

864 isostatically compensated and manifested in the present-day topography. If they are present

865 yet ignored and the topography is assumed to comprise only surface loads, then inversion of

866 the topography for isostatic model parameters will, again, yield incorrect parameter estimates.

867 But most importantly, transfer function (admittance) methods cannot properly account for

868 subsurface loads when they coexist with surface loads. This is true even if complex-valued

869 analytic transfer functions are employed that should, in theory, account for phase differences

870 between the two loads, but in practice do not. This suggests that more ingenious methods

871 must be devised in order to obtain more realistic isostatic anomalies.

872

873 Isostatic anomalies can also be inverted for the depth to the compensating density interface,

874 often assumed to be the Moho. Again, if T_e is ignored and an Airy isostatic model assumed,

875 then the Moho depth estimate will always be larger than the reality. This further affects

876 derived values of the dynamic topography when Moho depths are used for its estimation.

877 Coupled with an uncertainty of the role of subsurface loading, omission of T_e from analyses

878 can lead to very large overestimates, or moderate underestimates of the dynamic topography.

879 In addition to dynamic support, T_e plays a strong role in the mechanical support of

880 topography. The size of topographic load that can be supported by a plate, as opposed to

881 hydrostatically compensated, can be found by estimation of the Bouguer coherence transition

882 wavelength.

883

884 Given the noted shortcomings of local isostatic models, one must question their continued

885 use. If T_e and the degree of subsurface loading can be reliably estimated in a region then

886 derived isostatic anomalies will have slightly lower power than those obtained under the

887 assumption of Airy isostasy, especially for high values of T_e and predominantly surface

888   loading (compare Figs 1a and b, 2a and b). However, as no transfer function-based method

889   can ever model the gravitational attraction of the compensation with 100% accuracy (for T_e

890   and $F > 0$), non-zero isostatic anomalies will always be observed, and potentially

891   misinterpreted.

892

1072

1073   Table 1. Values of constants and parameters used in this study. Throughout the article the

1074   following density contrasts are used: $\Delta\rho_0 = \rho_c - \rho_f$ and $\Delta\rho_1 = \rho_m - \rho_c$.

1075

Constant	Symbol	Value
Gravitational constant	$\mathcal{G}$	6.67259×10^{-11} m^{3}kg^{-1}s^{-2}
Young's modulus	E	100 GPa
Poisson's ratio	ν	0.25
Gravity acceleration	g	9.79 ms^{-2}
Fluid density (air or sea water)	ρ_f	0 or 1030 kg m^{-3}
Crust density	ρ_c	2800 kg m^{-3}
Mantle density	ρ_m	3300 kg m^{-3}

1076

1077
1079

1080   Figure 1. The ratio of the isostatic anomaly standard deviation to that of the corresponding

1081   Bouguer anomaly ($\bar{\sigma}_{IA}$), from tests A, B and C. (a) Test A: synthetic models generated with

1082   the T_e and F values shown on the axes, and a compensation depth of $z_m = 35$ km;

1083   compensation attraction computed by incorrectly assuming Airy isostasy ($T_e = F = 0$), but the
1084   correct compensation depth. (b) Test B: synthetic models generated with the T_e and F values

1085   shown on the axes, and a compensation depth of $z_m = 35$ km; compensation attraction

1086   computed by incorrectly assuming surface loading ($F = 0$), but with the correct T_e and

1087   compensation depth. (c) Test C: synthetic models generated with the T_e and F values shown

1088   on the axes, and a compensation depth of $z_m = 35$ km; compensation attraction computed by

1089   correctly estimating T_e, F and compensation depth. Contour interval in all images is 0.05, and

1090   the maximum values of $\bar{\sigma}_{IA}$ in each of the panels are: (a) 2.14, (b) 0.36, (c) 0.30.
1091
Figure 2(a). Power spectra (versus wavelength λ) from some of the models in test A: synthetic models generated with the T_e and F values shown on the axes, and a compensation depth of z_m = 35 km; compensation attractions computed by incorrectly assuming Airy isostasy ($T_e = F = 0$), but the correct compensation depth. Bouguer anomaly (blue dashed); isostatic anomaly (red). The rows and columns correspond to the synthetic model T_e and F values in Fig. 1(a). The power spectra in this study were estimated by first computing 2-D power spectra using Slepian multitapers (K = 1 taper) of bandwidth parameter NW = 1 (e.g. Simons *et al.* 2000). Then, the 2-D power spectra were azimuthally averaged over annuli in

1102   the wavenumber domain for display as 1-D profiles. The multitaper parameters $K = 1$ and

1103   NW = 1 were chosen to maximise the wavenumber-domain resolution of the spectra (e.g.

1104   Kirby and Swain 2013). For these noise-free, synthetic data such low values of K and NW are

1105   acceptable, though for real data more tapers (higher values of K, and therefore also NW) may

1106   be preferable in order to improve the estimation variance (e.g. Simons *et al.* 2000).

1107

Figure 2(b). Power spectra (versus wavelength λ) from some of the models in test B: synthetic models generated with the T_e and F values shown on the axes, and a compensation depth of $z_m = 35$ km; compensation attractions computed by incorrectly assuming surface loading ($F = 0$), but with the correct T_e and compensation depth. Bouguer anomaly (blue dashed); isostatic anomaly (red). The rows and columns correspond to the synthetic model T_e and F values in Fig. 1(b).

Figure 2(c). Power spectra (versus wavelength λ) from some of the models in test C: synthetic models generated with the T_e and F values shown on the axes, and a compensation depth of $z_m = 35$ km; compensation attractions computed by correctly estimating T_e, F and compensation depth. Bouguer anomaly (blue dashed); isostatic anomaly (red). The rows and columns correspond to the synthetic model T_e and F values in Fig. 1(c).
Figure 3. Real and imaginary parts of the observed admittance of the synthetic model Bouguer anomaly and topography under Airy isostasy (a and b), surface-only loading (c and d), and combined loading (e and f). The T_e and F values at left are those from which the models were generated. The green dots show the estimates of the 2-D real and imaginary observed admittance plotted as functions of their radial wavenumber $k = |\mathbf{k}|$ (but displayed as wavelength). The blue curves show the theoretical 1-D real and imaginary admittance from eq. (24) for each (T_e, F) value indicated at left. The theoretical imaginary admittance curve in

1134   (f) has been reflected about the zero-admittance axis. The auto- and cross-spectra in the

1135   observed admittance were estimated using Slepian multitapers ($K = 3$, NW $= 3$). It was found

1136   that using $K = 1$ taper [as used to compute Fig. 2(a), for example; see Fig. 2 caption]

1137   produced admittance spectra that did not match the theoretical predictions; using 2 or 3, or an

1138   even higher number of tapers for any value of NW > 2 resulted in more faithful admittances.

1139
Figure 4. (a) The ratio of the isostatic anomaly standard deviation to that of the corresponding Bouguer anomaly ($\bar{\sigma}_{IA}$). Synthetic models were generated using the T_e values shown on the ordinate, surface-only loading ($F = 0$), and a compensation depth of $z_m = 35$ km; compensation attraction computed by incorrectly assuming Airy isostasy ($T_e = F = 0$), and with the compensation depth indicated on the abscissa. The red line in (a) shows the locus of the minimum standard deviation. Contour interval is 0.05, and the maximum value of $\bar{\sigma}_{IA}$ is 2.26. (b) The value of the best-fitting depth to Moho (z_m, in km) that minimizes the standard deviation of the isostatic anomalies. The synthetic models were generated with the T_e and F values shown on the axes (and a compensation depth of 35 km); the compensation (and therefore isostatic) anomalies were computed by incorrectly assuming Airy isostasy ($T_e = F = 0$) over a broad range of assumed compensation depths (indicated on the abscissa in Fig. 4a). The two red contours are 34.5 and 35.5 km, and so mark the regions where the model compensation (Moho) depth (35 km) is recovered almost exactly. Fig. 4(a) hence represents the results from a subset of Fig. 4(b), when $F = 0$.
Figure 5. Theoretical curves of the Bouguer coherence for five different T_e values (indicated, in km). In all cases the initial loading ratio, $f = 1$. Note how lithosphere with a high T_e has a long-wavelength Bouguer coherence rollover (from 1 to 0), and as T_e decreases the rollover migrates to shorter wavelengths.
Figure 6. (a) T_e (km), and (b) predicted Bouguer coherence transition wavelength (km) over Europe, with topography shaded relief superimposed. Lambert conic conformal projection.

Figure 7. Surface topographic amplitude as a function of load wavelength, corresponding to a Moho topographic amplitude of 1 km, for six different T_e values (indicated, in km). (a) Surface loading, from eq. (31). (b) Subsurface loading, from eq. (33).
