Abstract

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, has been determined as an independent risk factor for developing breast cancer. Previous studies have reported that the potential risk of breast cancer in women with dense breasts is three- to five-fold higher than in women with fatty breasts. Numerous MR breast-imaging protocols have been applied to the screening and/or the assessment of breast density, ranging from contrast- to non-contrast-enhanced imaging with or without the implementation of fat-suppression techniques. However, there has been little consensus on the optimal MR breast-imaging protocol and measurement method for breast density screening and/or assessment, especially in the context of women with dense breast tissues. The main aim of this study was to determine the most appropriate technical/operational MRI protocols for the quantitative assessment of breast density.

A systematic review and meta-analysis study was first conducted to review the existing measurement methods and breast-imaging protocols for the quantitative assessment of breast density using MRI over the previous decade of publications. Following this, a patient-specific breast model was developed using 3D-printing techniques and tissue mimicking materials to identify the most appropriate materials for simulating the MRI related-characteristics of fibroglandular and adipose breast tissues. Anthropomorphic shapes of skin and fibroglandular tissues were constructed using 3D-printing techniques based on the segmentations of breast MR images from a selected healthy patient's data. All the 3D skin and fibroglandular region shells were designed as hollow structures using polylactic acid (PLA) and photopolymer resin.

Then, using a personalized 3D-printed breast model and an objective comparison of the non-fat-suppressed and fat-suppressed sequences, an analysis was conducted to determine the most suitable MR breast-imaging protocols for the quantitative assessment of breast density. Finally, in a cohort of 11 high-risk women, a study was performed to investigate the difference between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density of two MR techniques, the non-fat-suppressed versus the fat-suppressed T2-weighted imaging sequences.

The following are some of the study's findings:

Results for the quantitative measurement of breast density using MRI: A systematic review and meta-analysis:

- The review of 38 studies confirmed high levels of heterogeneity within the breast density studies, mainly due to the applications of MR breast-imaging protocols and the use of different breast density segmentation/measurement methods.
- The analysis confirmed that the non-contrast-enhanced T1-weighted acquisition was commonly utilized among all MR breast-imaging protocols and the fuzzy C-mean clustering (FCM) is the most frequently used algorithm amongst the breast density segmentation/measurement methods.

Results for the development of patient-specific 3D-printed breast model using silicone and peanut oils for MRI:

- A patient-specific 3D-printed breast phantom was successfully designed and constructed using silicone and peanut oils to simulate the MR imaging characteristics of fibroglandular and adipose tissues.
- The silicone and peanut oils were found to closely resemble the T1 relaxation times and imaging characteristics of these two tissues, which are $1,515.8 \pm 105.5$ and 405.4 ± 15.1 ms, respectively.
- The agarose gel with different concentrations, ranging from 0.5 to 2.5 wt%, was found to have the longest T1 relaxation times.

Results for the quantitative measurement of breast density using personalized 3D-printed breast model for MRI:

- The volume of fibroglandular tissue and the percentage of breast density were significantly higher in the fat-suppressed sequences than in the non-fat-suppressed sequences ($p < 0.05$); however, the difference in breast volume was not statistically significant ($p = 0.529$).
- A fat-suppressed T2-weighted with turbo inversion recovery magnitude (TIRM) imaging sequence was superior to the non-fat- and fat-suppressed T1- and T2-weighted sequences for the quantitative measurement of breast density due to its ability to represent the exact breast tissue compositions.
- This study shows that the fat-suppressed sequences tended to be more useful than the non-fat-suppressed sequences for the quantitative measurements of the volume of fibroglandular tissue and the percentage of breast density.

Results for the quantitative measurement of breast density in a high-risk group using fat-suppressed and non-fat-suppressed T2-weighted MRI sequences:

- The results revealed no indication of measurement bias between the non-fat-suppressed and fat-suppressed T2-weighted imaging sequences with respect to breast density parameters, and no evidence to reject the presumption that the differences were normally distributed.
- Although the breast volume measured in the fat-suppressed T2-weighted sequence was slightly higher than that in the non-fat-suppressed T2-weighted sequence and the difference was close to significant ($p = 0.078$), the findings showed no significant difference in the breast density parameters analyzed from the two imaging techniques.
- This study showed no substantial differences between the non-fat-suppressed and fat-suppressed sequences in the quantitative measurement of breast density parameters; however, further studies with inclusion of a larger sample size are required to validate the complementary role of T2-weighted imaging in this regard.

In conclusion, this research has intensified the need for a standardized imaging protocol and/or measurement method for the evaluation of breast density predominantly for women at an elevated risk of developing breast cancer, such as those with high breast density. Using 3D-printing techniques and tissue mimicking materials, this study has suggested that silicone and peanut oils can be used to efficiently simulate the MR imaging characteristics of breast structures and produce further models. The proposed methodologies can be used as a preliminary work for breast structure simulations and the construction of further patient models using MRI dataset.

2 Acknowledgements

First and foremost, I would like to express my heartfelt gratitude to “God” for lavishing me with much more than I deserve.

I am deeply thankful to my supervisor Professor Zhonghua Sun for his patience, encouragement, enthusiasm, tremendous knowledge, and invaluable guidance during the research journey and writing of this thesis. He has been a fantastic mentor in helping me plan out my PhD journey, providing research advice, connecting me with resources, being available and responding to my emails and questions. Professor Sun is a pioneer in the field of Medical Radiation Science, and his extensive expertise in research and publication has been instrumental in my success.

I would like to thank Dr. Chai Hong Yeong and Dr. Yin How Wong from Taylor’s University in Malaysia for their assistance with the breast phantom construction and the use of the 3D printing facilities.

I appreciate Mr. Gil Stevenson, who, although no longer with us, for his unwavering support and assistance with the statistical analysis used in this project. He is one of the smartest people I have ever had the privilege of working with; he challenged me to think deeper, work harder, and seek out new opportunities.

I would also like to express my deepest appreciation to the Saudi Armed Forces Medical Service Division, the King Fahd Armed Forces Hospital, and the Saudi Arabian Cultural Mission for their financial support.

Last but not least, I owe a debt of gratitude to my family, brothers and sisters for their continued encouragement. Mrs. Rania Sindi, my soulmate, for her unwavering support, love, prayers, and devotion, without which I would not have made it through this project.

6 Introduction to Thesis

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, has been determined as an independent risk factor for developing breast cancer. To date different MR breast imaging protocols have been applied to the screening and/or the assessment of breast density, ranging from non-contrast-enhanced T1-weighted to contrast-enhanced T1-weighted and diffusion-weighted acquisitions. Along with this growth in the quantitative assessment of breast density using MR imaging, however, there has been no general agreement about the optimal technical approach in this aspect.

The applications of 3D printing in breast tissue are limited, therefore, a patient-specific 3D printed breast model could be used to examine different MR breast-imaging protocols. This can make a substantial contribution to the quantitative assessment of breast density by exploring the optimal protocol with this regard. An important implication of this is the possibility that breast density is assessed, thus, the risk factor of breast cancer can be identified to some extent.

The purpose of this study is to identify the optimal MR breast-imaging protocol and measurement method for the quantitative assessment of breast density. In more detail, this study aims to achieve the following objectives:

- Development of patient-specific breast model using 3D-printing techniques and tissue mimicking materials for MRI. This endeavours to identify the most appropriate materials for simulating the MR imaging characteristics of fibroglandular and adipose tissues, demonstrates the feasibility of creating a

realistic 3D-printed breast model for breast density assessment and further study.

- Quantitative measurement of breast density using a patient-specific 3D-printed breast model for MRI. This attempts to determine the optimal MR breast-imaging protocol for assessing breast density quantitatively, taking into account a variety of imaging techniques, acquisition modes, and fat-suppression methods. This entails a review of the usefulness, applicability, ease of use, and outcomes of a semi-automated approach for segmenting and measuring breast density parameters.
- Quantitative measurement of breast density in participants' clinical breast MRI datasets. This aims to investigate the difference between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density of two MR techniques, the non-fat-suppressed versus the fat-suppressed T2-weighted imaging sequences.

7. Thesis Outline

The thesis is divided into six chapters in its overall structure. Chapter 1 is the introductory background for this study. It includes a summary of the importance role of MRI in breast density screening and evaluation, as well as a literature review of current MRI protocols and segmentation/measurement for breast density assessment. This chapter concludes with a discussion of existing 3D printing technologies and MRI breast phantoms. Chapter 2 is the chronologically first publication and is entitled “Quantitative Measurements of breast density using magnetic resonance imaging: A

systematic review and meta-analysis”. Chapter 3 is the chronologically third publication and is entitled “Development of patient-specific 3D-printed breast phantom using silicone and peanut oils for magnetic resonance imaging”. Chapter 4 is the chronologically fifth publication and is entitled “Quantitative measurement of breast density using personalized 3D-printed breast model for magnetic resonance imaging”. Chapter 5 is the “Quantitative measurement of breast density in a high-risk group using fat-suppressed and non-fat-suppressed T2-weighted magnetic resonance imaging sequences”. Finally, Chapter 6 is a list of observations, which includes a concise summary and critique of the findings as well as potential future directions.

8 Statistical Analysis

In chapter 2, a single arm meta-analysis was conducted to determine the quantitative values of MRI in breast density assessments. Combined means with their 95% confidence interval (CI) were calculated using a fixed- effect model. A forest plot was generated, displaying the individual study (% breast density) means with 95% confidence interval (CI) limits, inverse variance study weights, and the pooled mean and confidence limits. The data was analyzed by the “metamean” function in the “meta” package in the R system, Version 3.4.1 (<http://www.r-project.org/>). Heterogeneity of study means was assessed using Cochran’s Q-test, and heterogeneity of study variances was assessed with Bartlett’s test. A conclusion to pool studies requires both heterogeneity tests to be non-significant at the 5% level

Furthermore, alternative groupings based on statistical similarities were identified via a cluster analysis employing study means and standard deviations in a Nearest Neighbor/Single Linkage. The International Business Machines Statistical Package for the Social Sciences (IBM SPSS) Statistics software Version 25.0 was used for cluster analysis.

In chapter 4, the repeated-measures analysis of variance (ANOVA) was performed to examine the difference between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density with regard to the non-fat-suppressed and fat-suppressed MRI sequences. This variance model was employed to account for the variation both between sequences (i.e., between subjects) and within repeated measurements (i.e., within subjects). Significance levels were set at the 5% level. Descriptive data and box plots were also produced for all variables, demonstrating the distribution and median of breast volume, fibroglandular tissue volume, and percentage of breast density measured in the non-fat-suppressed and fat-suppressed imaging groups. Statistical analyses were conducted using NCSS V 19.0.5 (NCSS, LLC., Kaysville, UT, USA).

In chapter 5, averages of repeated-measures observations through the Bland-Altman comparison of measurements were conducted to examine the difference between the non-fat-suppressed T2-weighted TSE and the fat-suppressed T2-weighted STIR MRI sequences with regard to the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density. The Bland-Altman scatter plots were produced for the two MRI sequences, demonstrating the difference against the average, which illustrates a system with zero bias of one method relative to the other with respect to breast volume, fibroglandular tissue volume, and

percentage of breast density. The normality assumptions of the datasets distributed were also examined using the Shapiro-Wilk, Skewness, Kurtosis, and Omnibus tests. Statistical significance was evaluated using the one-sample t-test as appropriate and set at the 5% level.

Statistical analyses for chapters 4 and 5 were conducted using NCSS V 19.0.5 (NCSS, LLC. Kaysville, UT, USA).

Figure 4.3. Box plots demonstrate the distribution and median of three main parameters: **(A)** breast volume, **(B)** fibroglandular tissue volume, and **(C)** percentage of breast density measured on the non-fat-suppressed and the fat-suppressed MRI sequences. The six MRI sequences compartments were re-configured into a two-way cross-classification, namely two fat-suppression categories. As shown, “1/No” is the non-fat-suppression, “2/Yes” is the fat-suppression, which are on the x-axis, while the three parameters measured with respect to these two corresponding categories are on the y-axis. 121

Figure 5.1. Bland-Altman plots for the breast density parameters agreement analysis (N = 11). **(A)** breast volume, **(B)** fibroglandular tissue volume, and **(C)** percentage of breast density measured from the non-fat-suppressed T2-weighted TSE and fat-suppressed T2-weighted STIR MR sequences. The average of the breast density parameters of the two sequences is on the x-axis, while the estimated mean difference (a measure of the bias between the two sequences) is on the y-axis. Limits of agreement are shown as solid, black lines with 95% confidence intervals (as light dotted black line), and bias (as dark dotted black line) with 95% confidence interval.

Note that the limits of agreement are calculated as the mean difference ± 1.96 Std Dev, where the Std Dev is determined from the array of difference value. The factor 1.96 indicates the assumption that the difference values are normally distributed. The upper and lower limits of the agreement 1.96 Std Dev are displayed above and below zero, not the mean difference. The differences between the two MRI sequences and their averages are listed in Table 5.3, while the Bland-Altman analyses, including the bias and limits of agreement are in Table 5.5..... 146

Figure 5.2. Scatter plots display the degree of agreement between the non-fat-suppressed T2-weighted TSE and the fat-suppressed T2-weighted STIR MRI sequences for (A) breast volume, (B) fibroglandular tissue volume, and (C) percentage of breast density. The breast density parameters (A, B, and C) measured from the fat-suppressed T2-weighted STIR MRI sequence are on the x-axis; from the non-fat-suppressed T2-weighted TSE MRI sequence are on the y-axis. The dotted black line shows the line of equality (i.e., the line of perfect agreement); the Bland-Altman correlation of 1 indicates perfect agreement, while the value of 0 indicates complete discord. The level of agreements between the two MRI sequences are listed in Table 5.4, with a correlation coefficient of 0.990 for breast volume, 0.458 for fibroglandular tissue volume, and 0.858 for percentage of breast density. 149

1. Chapter 1

Background and Literature Review

1.1 Breast Density and Classification

Breast density, a measure of fibroglandular, dense tissue relative to fatty, non-dense tissue, is an independent risk factor of breast cancer.¹⁻³ Consistent with this risk relationship, women who have dense breasts have a likelihood of developing breast cancer that is fourfold higher than those with fatty breasts.^{4,5}

The evaluation of fibroglandular tissue is based on a subjective assessment recommended by the American College of Radiology (ACR) Breast Imaging-Reporting and Data System (BI-RADS), which is commonly used for mammography but also for magnetic resonance imaging (MRI). The BI-RADS Atlas can be described as a classification system that characterises breast density on the basis of the amount of fibroglandular tissue into four categories: 1) almost entirely fat, 2) scattered fibroglandular tissue, 3) heterogeneous fibroglandular tissue, and 4) extreme fibroglandular tissue.^{6,7}

1.2 Imaging Modalities for Breast Density Assessment

Most information about breast density estimation and screening for breast cancer is obtained through full-field digital mammography (FFDM), a two-dimensional (2D) imaging technique. FFDM is considered an effective screening modality that can contribute to the reduction of breast cancer mortality, particularly at an early stage of the disease.^{8,9} However, the evaluation of breast density based on mammograms is limited due to tissue overlapping, variations in breast compression, and inappropriate positioning, which can lead to artefacts (skin folds) and insufficient imaging of breast tissue.^{10,11} Another problem with this modality is its low sensitivity in detecting breast cancer when the breast tissue is dense, which is the case for 40% to 50% of women

under the age of 50 years.¹² Kolb et al¹³ found that as breast density increases, the sensitivity in detecting breast cancer is decreased from 89% in fatty breasts to 42% in women with over 75% mammographic density. These factors can limit mammography's precision and reliability for the detection of small changes in breast density over brief timespans.^{14, 15}

1.2.1 Digital Breast Tomosynthesis

To address the limitations of conventional mammography, digital breast tomosynthesis (DBT) has been developed, which enables three-dimensional (3D) reconstructions of the breast volume and has become one of the most widely imaging tools in breast centres worldwide.^{16, 17} Recent research has shown a dramatic improvement in screening outcomes of breast density assessments with this technique.¹⁶⁻¹⁹ It provides high-resolution imaging, higher diagnostic accuracy, and better detection rates compared to conventional digital mammography.^{20, 21} DBT differs from conventional two-dimensional mammography in several respects. In FFDM, the planar information is obtained from multiple projection images. As each scan can create only one image plane, multiple scans are required to reconstruct the whole breast.^{22, 23}

In contrast, in DBT, the planar information is obtained using only one set of X-ray projections at various angles; therefore, one scan can produce a 3D reconstruction of all planes, creating a full breast volume.²⁰⁻²² However, despite differences of opinion, there appears to be some agreement that 2D images are still essential, as some microcalcification clusters are not easily detectable in 3D images.⁸ The US Food and Drug Administration (FDA) has recommended that DBT be used in combination with FFDM to enhance the diagnostic reliability and screening performance of standard

mammography.^{22, 23} However, a major problem with this recommendation is the exposure of patients to a double radiation dose, as the radiation exposure of DBT is comparable to that of FFDM.^{8, 22, 23} Therefore, there seems to be a need for wider acceptance of DBT in breast screening to limit radiation exposure.

1.2.2 Breast Ultrasonography

Breast ultrasonography (US), a non-ionizing technology, is an important imaging modality for breast cancer detection. It has played a key role in image-guided biopsy and lymph node diagnosis for a long time, as it is inexpensive and widely available.^{25, 26, 30} A variety of ultrasound imaging techniques have been used for breast cancer detection, which can be classified into five main categories: ultrasound-based elastography, contrast-enhanced ultrasound, 3D ultrasound, automated breast sonography, and computer-aided detection of breast lesions.²⁵⁻³⁰

For breast density assessments, two types of automatic breast volume scanning have been used as a tool complementary to mammography, each with its advantages and disadvantages: hand-held ultrasound (HHUS) and automated breast ultrasound (ABUS).^{25, 29, 30} HHUS is a novel technique for breast tissue characterization that uses a conventional US system and a passive reflector, which is placed at the opposite side of the US probe. The purpose of the passive reflector is to measure the speed of sound in tissue and reflect it back to the US probe.^{29, 30} However, due to practical constraints, HHUS cannot yield reproducible results or image and/or store 3D volumes of the breast. Other major drawbacks of this approach are that it cannot reconstruct the whole breast and that it largely relies on the operator's skills.^{29, 30}

ABUS, also known as automated breast volumetric scanning (ABVS), was approved by the US FDA in September 2012 and has been used in various studies for 3D ultrasonographic depictions of the whole-breast structure to assess breast density.^{25, 26} The ABUS technique is one of the more practical methods of breast density analysis, as it can provide true volumetric imaging data. The concept of this modality is based on combining breast echoic reflex images to produce multiplanar whole-breast reconstructions.^{25, 27} Most of the breast structure, such as the skin, subcutaneous fat, fibroglandular tissue (FGT), mamilla, retromammary fat, muscle fascia, and ribs, can be clearly visible in ABUS images.²⁶ Several studies have shown that the echogenicity and speed of sound tend to be higher in FGT than in subcutaneous and retromammary fat.^{26, 28, 29} This provides the ability to differentiate between FGT and other breast structures in surrounding tissue, thus enabling more accurate breast density measurements. ABUS can mainly be applied in women with high breast density, no previous invasive procedures, and a BI-RADS score of 1, which indicates negative cancer results on X-ray mammography.^{25-28, 30} However, despite its increasing popularity for breast density assessments, ABUS has certain limitations, such as its reliance on a dedicated ultrasound system and custom add-on software.^{28, 29} Therefore, further studies should be conducted to determine the exact utility of this novel technique for breast density assessments and as a biomarker for breast cancer.

1.2.3 Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is one of the most widely used methods for breast cancer detection, in conjunction with mammography, US, and image-guided needle biopsy. It has been extensively applied for the screening of women at high risk of breast cancer, preoperative staging of newly diagnosed breast cancer (ipsilateral and

contralateral), evaluation of women with breast implants, and breast cancer treatment follow-ups.³¹⁻³³ The European Society of Breast Imaging (EUSOBI) has recommended that breast MRI be used as an adjuvant modality in women at high risk of developing breast cancer, such as those with breast cancer susceptibility gene (BRCA)-positive genetic mutation carriers, a family history of breast cancer, and/or high breast density.^{33, 34} Previous studies have reported that the sensitivity of MRI for breast cancer is up to 98% for invasive and 60–80% for ductal in situ breast carcinomas.^{32, 33} Several studies have also shown that MRI can detect enhancing invisible in mammography and US, 50% of which are cancerous.^{32, 33}

1.3 MRI Protocols for Breast Density Assessment

1.3.1 Dynamic Contrast-Enhanced Imaging

To date, various breast MRI protocols have been developed. The dynamic contrast-enhanced (DCE)-MRI technique is the most frequently used for the screening of women at high risk of breast cancer and has been included in standard clinical breast MRI protocols.^{35, 36} The sensitivity of this technique for breast characterization tends to be very high, in the range of 94–100 %, whereas its specificity is relatively low, ranging between 40 % and 80%.³⁷ Despite its long clinical success, DCE-MRI has certain disadvantages, such as long scanning time, high cost, and potential harm caused by the contrast agent.³⁷ Although contradictory findings have been reported in the literature about the precipitation and accumulation of gadolinium contrast-based agents in the brain, there is no general agreement regarding the risk of repeated gadolinium administration.³⁶ Nevertheless, questions have been raised about the safety of prolonged use of DCE-MRI as a primary screening method for breast cancer. On the other hand, despite considerable new knowledge about the role of MRI in breast

screening, many studies have reported the role of MRI in breast density analysis.³⁶ It has been used for qualitative and/or quantitative evaluations of breast density because it provides a three-dimensional volume image of breast tissue with excellent soft tissue contrast, which assists in the differentiation between fibroglandular and fatty, or adipose, tissue.^{12, 38-40}

1.3.2 Diffusion-Weighted Imaging

Diffusion-weighted imaging (DWI) is a non-contrast-enhanced MRI technique that measures Brownian motion, that is, random movements of free water molecules in all directions.^{35, 41, 42} Evidence suggests that the diffusion of water molecules is greatly affected by the tissue's cellularity.^{35, 41, 42} Restricted diffusion generally occurs in tissue with higher cellular density, as water molecules cannot diffuse easily within the tissue, bouncing back towards the impermeable cell walls.^{35, 41, 42} This phenomenon is observed in most cancers and is associated with high intensity on DWI.^{35, 41, 42} Apparent diffusion coefficients (ADCs), also known as estimated diffusion rates, calculated from DWI, play an important role in the differentiation between benign and malignant breast lesions.³⁵ Several studies exploring DWI as a screening tool supplemental to mammography have reported its advantages for breast cancer detection, predominantly in high-risk women with dense breasts.^{35, 43, 44} As an unenhanced MRI technique, DWI has been proposed as an alternative to DCE-MRI in terms of safety and cost related to the exposure to gadolinium contrast-based agents.^{35, 41, 42} However, breast DWI technique has not been standardized yet, and more research is required to determine its value as an adjunct screening tool in women at high risk of breast cancer.

1.3.3 Non- and Fat-Suppression T1-Weighted Imaging

Non-fat-suppressed and fat-suppressed T1-weighted images are frequently used either with 2D spin echo (SE) or 3D gradient echo (GRE) in standard clinical breast MRI protocols.^{36, 45} However, there is no consensus about the optimal protocol in this regard. The American College of Radiology (ACR) has recommended that fat-suppressed images with high spatial resolution be used in clinical breast MRI protocols, as the evaluation of fat-suppressed sequences based on the acquisition of post-contrast images without subtraction can eliminate misregistration, which mainly occurs when a patient moves during the acquisition of pre- and post-contrast images.^{36, 45} However, this recommendation is at odds with that of the EUSOBI, which considers non-fat-suppressed sequences based on the acquisition of subtraction images more useful.^{45, 46} In fact, non-fat-suppressed images tend to have a higher signal-to-noise ratio (SNR) and stronger tissue contrast than fat-suppressed images.^{45, 46}

Although non-fat-suppressed T1-weighted acquisition is commonly included in standard clinical MRI protocols to better visualize the breast's anatomy and fat distribution, there appears to be some agreement that other breast MRI techniques, including T2-weighted images, DCE, and DWI, tend to benefit from its combination with fat-suppression techniques for several reasons.^{1, 36, 45, 47} First, fat tends to appear bright in T2-weighted images due to its long T2 relaxation time. Therefore, if the fat signal is not completely eliminated, it can obfuscate the features of interest and interfere with the assessment of benign lesions.^{1, 36, 45, 47} Second, an unsuppressed fat signal can induce a chemical shift artefact caused by signal variations due to the inherent differences in resonant frequency between fat and water, usually observed on fat and soft tissue boundaries.^{45, 47, 48} Third, fat appears hyperintense on DCE-MRI

because of its comparatively short T1 relaxation time. If the fat signal is not completely suppressed, it can obfuscate the enhancing lesions and interfere with the variations of signal intensity caused by the contrast agent.^{45, 47, 49} It can thus be suggested that fat suppression is a very important technique to better visualize the enhancing lesions on DCE-MRI.⁴⁹ Furthermore, breast MRI is more susceptible to the inherent magnetic field (B_0) inhomogeneity caused by the difference in magnetic susceptibility between breast tissue and the surrounding air.^{48, 50} Therefore, the fat-suppression technique could be a reasonable approach to tolerate the B_0 inhomogeneity.^{48, 50} Finally, fat suppression has received considerable critical attention in breast DWI, which is largely based upon an echo-planar imaging (EPI) sequence.^{50, 53, 54} In a single-shot EPI, all the spatial-encoding data of an image can be obtained after a single radio frequency excitation in a few seconds. However, a main issue with this application is that chemical shift artefacts can lead to a significant displacement of the fat signal in the phase-encoding direction of EPI.^{50, 53, 54} Therefore, since the breast consists of a considerable amount of fat, fat suppression is necessary to eliminate its signal in breast DWI.^{50, 53, 54} Fat suppression has proven to be an essential component of DWI for different parts in the body, as it assists to overcome the limitations associated with fatty tissue.^{50, 53}

1.3.4 Fat-Suppression Imaging

Fat suppression is used in breast MRI to improve the visibility of pathology, contrast enhancement, and image quality, thus allowing a better differentiation between fatty non-glandular and glandular tissue.^{45, 47} It has been combined with other techniques because of the difficulty of eliminating the high signal intensity associated with fatty tissue.^{45, 47} Over the years, several methods have been proposed for fat suppression in

breast MRI, including chemical shift spectral-selective saturation (CHESS), which relies on the chemical shift variation between fat and water, inversion recovery (IR), which relies on the variation of T1 relaxation time, hybrid CHESS–inversion recovery methods, and Dixon fat-water separation, which relies on the phase variation between fat and water signals at different echo times (TEs).^{3, 41, 42, 45, 47, 55}

In CHESS, also known as fat saturation (Fat Sat), a 90° frequency-selective excitation pulse followed by a homogeneity spoiler gradient is applied to saturate/dephase the fat protons only, thus suppressing the fat signal while leaving the water signal relatively unaffected.^{47, 56-59} Although the CHESS technique has been successfully used in breast MRI, it has certain limitations related to its higher sensitivity to the inhomogeneity of the magnetic (B_0) and radio frequency (B_1) fields, which can cause significant heterogeneity in fat suppression.^{47, 56-59} Another limitation of this approach is that it cannot be implemented at each pulse repetition time (TR) on a repeated series of pulses and echoes in a fast GRE acquisition. Consequently, the steady-state signal and the quality of fat suppression can be affected even if the B_0 is completely homogeneous across the entire field of view.^{56, 59} Fat suppression based on CHESS or other chemical shift selective excitation techniques can be improved by using a high-field MRI system ($\geq 3T$), especially with the acquisition of a GRE pulse sequence.^{47, 56, 60} This is because the chemical shift difference between fat and water at higher magnetic field strengths is increased, achieving B_0 and B_1 homogeneity. Nevertheless, field heterogeneity is more prominent in 3T MRI systems, which inevitably affects the fat suppression performance and image quality.^{47, 56, 60}

In an inversion-based technique known as short TI inversion recovery (STIR), a 180° non-spectral-selective inversion pulse is applied, followed by either a single 90° pulse or a pair of 90° and 180° pulses for the IR and SE imaging, respectively.^{47, 56, 58, 61, 62} The time between the 180° inversion pulse and the subsequent 90° pulse is referred to as inversion time (TI), which for fatty tissue is assumed to be 180 and 215 ms for 1.5T and 3T MR systems, respectively.^{47, 56, 58, 61, 62} During the TI interval, the T1 relaxation time of fat is shorter than that of water, and thus fat is recovered faster. Subsequently, at the 90° excitation pulse, the fat signal is nulled out, and a fat-free signal is produced.^{47, 56, 58, 61, 62} Because of the expected longer T1 relaxation time of water, more time is required for the signal to reach the null point; consequently, it is attenuated and/or reduced.^{47, 56, 58, 61, 62} STIR sequences are among the most widely used fat-suppression techniques in breast imaging due to their insensitivity to B₀ and B₁ heterogeneity.^{47, 62} However, STIR suffers from major drawbacks, including its long imaging time, low SNR, and high specific absorption rate (SAR) of the radio frequency energy.^{41, 47, 56, 58, 61, 62} Another considerable disadvantage is that, because STIR is not a fat-specific suppression technique and relies on the variation of T1 relaxation times, during the TI interval, it can also suppress all other tissues and substances with a short T1 relaxation time along with fat tissue.^{47, 56, 58, 61, 62}

Regarding hybrid approaches, two fat-suppression techniques have commonly been used: spectral pre-saturation with inversion recovery (SPIR) and spectral pre-saturation attenuated with inversion recovery (SPAIR).^{41, 47, 62} In SPIR, an 180° spectral-selective inversion pulse is applied for fat only, followed by a single 90° excitation pulse after a certain TI.^{41, 47, 62} Clear benefits of SPIR are that it has a higher SNR than purely inversion-based techniques and that it does not suppress other tissues with short T1 relaxation times, as the latter do.^{41, 47, 62} Despite its advantageous fat-

suppression approach, SPIR still suffers from B_1 inhomogeneity due to the expected variation of the radio frequency amplitude across the entire field of view.^{41, 47, 56, 58, 61, 62} On the other hand, in SPAIR, an 180° spectral-selective adiabatic inversion pulse is applied for fat only, followed by a single 90° excitation pulse after a certain TI.^{41, 47, 62} The purpose of the adiabatic radio frequency pulse is to reduce the radio frequency amplitude variations, thus mitigating the B_1 inhomogeneity and providing more uniform fat suppression than CHESS and STIR, particularly in high-field MRI systems.^{41, 47, 56, 58, 61, 62} Overall, perhaps the most obvious advantage of using hybrid methods for fat suppression in breast MRI is their higher SNR, since SPIR and SPAIR are fat-selective techniques.^{41, 47}

In the Dixon technique, also known as fat-water separation, two separate images can be produced based on the resonant frequency difference between fat and water, by combining an in-phase and an opposed-phase GRE image at different TEs.^{41, 47, 55, 57} As fat and water can be specifically constructed, the sum of the fat and water signals generates a water-only image, while the difference between them generates a fat-only image.^{41, 47, 55-60} A significant advantage of the Dixon technique is its lower sensitivity to the B_0 and B_1 inhomogeneity – especially in high-field MRI systems, where the heterogeneity is more pronounced – which enables more uniform fat suppression.^{41, 47, 55, 57} In addition, it can be implemented with various pulse sequences in breast imaging.⁵⁹ In view of its advantages, fat-water separation is a highly recommended sequence among fat-suppression methods for breast imaging, as it can be used to specifically image the water that corresponds to the FGT, thus allowing an optimal assessment of breast density.^{41, 47, 55-60}

1.4 MR Breast Density Segmentation/Measurement Methods

Conventionally, breast density assessment is based on a qualitative approach using the ACR BI-RADS Atlas, which classifies density into four categories based on the amount of FGT.^{6, 7} Despite its long clinical success, BI-RADS scores are subjective, resulting in inter- and even intra-reader variability.⁶³⁻⁶⁵ To overcome this issue, several methods and algorithms have been proposed for quantitative breast density assessments.⁶⁶⁻⁷²

While various definitions of the term “breast density” have been proposed, in this context, the term “fibroglandular tissue” (FGT) is used to refer to breast density. Indeed, breast density is measured as the percentage of FGT volume to the total breast volume.¹⁻³ Two steps are required to quantify the FGT volume from MRI data: breast segmentation and FGT segmentation.^{38, 72} Breast segmentation distinguishes the breast’s body from the surrounding tissue, including the pectoral muscle, heart, lungs, and thorax. FGT segmentation distinguishes parenchymal from adipose tissue.^{38, 66, 72} Several methods have been developed to segment the FGT in breast MRIs, which can be categorized into four conceptual models: a clustering algorithm, an interactive thresholding algorithm to segment glandular and fatty tissue, a logistic function approach, and a curve-fitting algorithm.^{36, 66-72}

Clustering algorithms classify breast regions into clusters/groups displayed in a histogram using a code based on greyscale intensity. As an unsupervised algorithm, each voxel is assigned to a cluster. In other words, all voxels in the segmented breast are assigned a code representing the FGT content with different greyscale tones.^{12, 38} An updated version of this algorithm, the fuzzy C-means (FCM) clustering algorithm, is one of the most common methods used to separate FGT from fatty tissue in breast

MRI.³⁶ It has also been combined with the non-parametric non-uniformity normalization (N3) algorithm for image inhomogeneity and/or bias field correction.^{67,}

⁶⁸ The N3 algorithm is used for non-parametric non-uniform intensity normalization to adjust the signal intensity variations within the same structure.^{67, 68}

Interactive thresholding algorithms categorize the breast voxels according to a threshold value usually specified by the radiologist. The breast voxels are classified into two groups: voxel values above the threshold correspond to dense tissue, while voxel values below the threshold correspond to fat tissue. Breast density is calculated as the number of voxels in the dense area divided by the total number of voxels across the whole breast region.⁷⁰ The logistic function approach, or Bayesian probability, estimates the highest-probability combination of materials within each voxel-sized region. Then, the possible tissue types within each voxel are identified, and continuous “basis” functions are assumed to represent the probability that a particular voxel contains a specific type of tissue.⁷¹

The curve-fitting algorithm technique compares breast tissue to a mixture model known as the 3D volume-rendered breast model, whereby all MR voxel signal intensities are extracted from the 3D model to generate a signal intensity histogram. On that basis, a two-compartment model of breast tissue compositions can be constructed. The histogram of the MRI signal intensities usually contains two major peaks: one corresponds to adipose tissue, and the other to non-adipose tissue. The sum of voxels represents the FGT.⁷⁰

Each of the aforementioned semi-automatic thresholding and segmentation approaches has its own advantages and limitations in the quantitative assessment of breast density.⁶⁶⁻⁷² No consensus has been reached about the best method to date.³⁶

1.5 3D Printing Technology

The last decade has seen significant advances in 3D printing technology, also known as additive manufacturing, rapid prototyping, or solid freeform fabrication.⁷³⁻⁷⁸ It is used in various medical applications, including cardiovascular disease treatment, orthopaedic surgery, prosthetics, and neurosurgery.⁷³⁻⁷⁸ Prosthetics was the first biomedical field to take advantage of 3D printing, with considerable achievements in terms of improved visualization and surgical outcomes.^{79, 80} Patient-specific guides and 3D-printed anatomical models and prostheses derived from either computed tomography (CT) or MRI data have assisted in developing surgical implants, practising procedures, teaching students, and improving the individual's understanding with precise reproductions of complex anatomical structures and pathologies.^{73-78, 81, 82} The technology's main advantages are shorter surgical times, reduced radiation exposure, and improved diagnosis and outcomes.^{73, 81}

Additive manufacturing can be generally described as the construction of an object's components by placing a material on a certain kind of building platform.⁷⁹⁻⁸² It starts with a meshed 3D computer model that can be generated through the acquisition of image data and/or structures, mostly designed using computer-aided design (CAD) software.⁸⁰⁻⁸³ Standard Tessellation Language (STL) is the standard file format for storing 3D models.⁸⁰⁻⁸³ The mesh data is further divided into a 2D-layered build file and fed into the 3D printer.⁸⁰⁻⁸³ Various additive manufacturing techniques have been extensively used for fabricating polymer composites and other composite materials, each with its own advantages and disadvantages.⁸⁰⁻⁸³ Multiple factors determine the appropriate additive manufacturing technique, such as raw materials, processing

speed, resolution requirements, costs, and performance specifications of the final product.⁸⁰⁻⁸³

Additive manufacturing techniques can be classified into three categories: selective binding, selective solidification, and selective deposition.^{79, 80, 82} Selective binding technologies render a 3D-printed object from a powder (thermoplastic powders are the most common) using binding agents or heat to bind the powder's particles together.^{79, 80} An example is selective laser sintering (SLS), whereby constructive layers of powdered material are fused by a laser.⁷⁹⁻⁸³ The first layer is melted to a base; then, another thin layer is deposited on top of it. The process is repeated until the model construction is complete⁷⁹⁻⁸³. The powder serves as a print support medium; therefore, highly complex and precise prints can be produced.⁷⁹⁻⁸³ However, fine powders can be difficult to handle, and printers based on the SLS technique are often expensive.⁷⁹⁻⁸³ The resolution of SLS 3D-printing technology is mainly determined by the material's particle size, laser strength, scan spacing, and scanning speed.⁸⁰⁻⁸³

Selective solidification technologies render a solid object of a liquid vat under a light source (photopolymer resins are the most commonly used materials), where constructive layers of liquid photopolymer resin are solidified using selective energy.^{79, 80} The first layer is usually constructed on a kind of building platform that is elevated onto a resin tank, a light source, and galvanometers.⁷⁹⁻⁸⁶ Examples are stereolithography (SLA), which uses a laser to solidify the resin with ultraviolet (UV) light, and a digital light projection (DLP) imager used to stiffen each layer⁷⁹⁻⁸⁶. In both approaches, the mould needs to be cured thereafter, and the resin can be challenging to handle.⁷⁹⁻⁸³ The main benefit of SLA 3D printing is its capability of producing models with high resolution and/or quality.⁸⁰⁻⁸³ Furthermore, as a nozzle-free

technique, it eliminates nozzle clogging.⁸⁰⁻⁸³ Nevertheless, the main disadvantages are its high cost, which can be a significant concern for industrial and medical applications, and its potential cytotoxicity of the uncured resin and the residual photoinitiator.⁸⁰⁻⁸⁴

In selective deposition technologies, a layer-by-layer deposition of a molten polymeric material on a building platform is the working concept, whereby a heated nozzle moves at the xyz axis, where layers are fused and then solidified into the final object.⁷⁹⁻⁸⁵ Thermoplastic filaments are the most commonly used materials owing to their melting temperature.^{79-83,85} An example is fused deposition modelling (FDM), also known as fused filament fabrication (FFF).^{79, 80} Filament-based printers melt a filament into a semi-liquid and deposit it precisely to create an object⁸⁰⁻⁸³. Other 3D printers use liquid resin with inkjet, which is then cured with UV light.⁸³ Some printers combine the selective binding and selective deposition techniques using a powder mixed with a binder.⁷⁹⁻⁸³

FDM/FFF is one of the most used approaches for rapid prototyping, primarily due to the wide availability of cheap printers with high speed, simplicity, and low operation costs.^{80, 81, 84} An important drawback is that the composite materials need to be in a filament shape to facilitate the extrusion process and are limited to thermoplastic polymers with melt viscosity high enough for structural support and low enough to allow extrusion.⁸⁰⁻⁸⁴ It can thus be difficult to remove the supporting structures when the printing process is completed.⁸⁰⁻⁸⁴ Comparison of different types of 3D-printing techniques, including their advantages and disadvantages are summarized in Table 1.1.

Table 1.1. Comparison of different types of 3D-printing technologies.⁷⁹⁻⁸⁶

Technology	Approach	Principle	Materials	Layer Thickness	Advantages	Disadvantages
SLS	Laser and heat induced sintering.	Localized powder melting.	Thermoplastic powder: Nylon (e.g., PA), steel, titanium, alloys, and ceramic powders.	25-92 μm .	-No requirement of pre-designed support structure. -Good strength of produced parts. -Low UV radiation. -Less post-processing.	-Parts may suffer shrinkage and warpage due to sintering and cooling. -Powder can get into vulnerable areas, inducing health problems. -High cost.
SLA	Laser and UV induced curing.	Localized co-polymerization.	Photopolymer resins (e.g., epoxy or acrylate-based resin), with high-temperature resistant resins.	< 10 μm .	-High resolution. -Nozzle-free technology.	-Cytotoxicity of residual photoinitiator and uncured resin. -Misuse of liquid resins constitutes a risk, and ingestion is hazardous. -Post-processing is required to remove support materials. -High UV radiation. -High cost.
FDM/FFF	Extrusion and deposition.	Liquified polymers using nozzles.	Thermoplastic filament: ABS, PLA, PVA, PC, HIPS, PETG, and Nylon (e.g., PA).	100-250 μm .	-Low cost. -Good strength of produced parts. -Deposition of different materials. -Printed parts are multi-purpose. -No use of UV radiation.	-Low resolution on the z axis relative to other 3D printing technologies. -It may require days to produce through, complicated pieces for a slow operation. -Should be in a filament format. -Homogeneity lack for the disperse material. -A limitation with nozzle clogging. -Post-processing is required to remove support materials.

Abbreviations: SLS: selective laser sintering; SLA: stereolithography; FDM: fused deposition modelling; FFT: fused filament fabrication; PA: polyamide; ABS: acrylonitrile butadiene styrene; PLA: polylactic acid; PVA: polyvinyl alcohol; PC: polycarbonate; HIPS: high impact polystyrene; PETG: polyethylene terephthalate (glycol).

Table 1.1. Continued.^{74,80, 82}

Technology	Approach	Principle	Materials	Layer Thickness	Advantages	Disadvantages
PolyJet	Laser and UV induced curing.	Polymerization of deposited droplets of photopolymer ink.	Photopolymer resins.	25-50 μm .	-High resolution. -Good surface finish and smoothness.	-Post-processing is required to remove support materials. -High cost. -Slow speed.
3DP/CJP	Powders and binders.	Drop-on-demand binder printing.	Powder.	100-400 μm .	-Low cost. -Multi-material capability. -Supporting material can be easily removed.	-Clogging of binder jet. -Binder contamination. -Printing resolution is limited.

Abbreviations: 3DP: three-dimensional printing; CJP: colour jet printing.

1.6 MRI Breast Phantom

A breast phantom comparable to the anatomical structures of human tissues can be a valuable tool for examining different breast MRI protocols, test the radio frequency coils, and evaluate system performance.⁸⁷⁻⁹⁴ Such a phantom should resemble the MR-related characteristics of T1 and T2 relaxation times that are analogous to those of the simulated tissue and load the radio frequency coils electrically as real tissue.⁸⁷⁻⁹⁴ Further, it should be made from appropriate materials to produce precise shapes and/or sizes of such complex anatomical structures.⁸⁷⁻⁹⁴ These materials should ideally be affordable, readily accessible, and easy to process.⁸⁷⁻⁹⁴ More broadly, the phantom should also maintain its chemical and physical characteristics over an extended period.⁸⁷⁻⁹⁴

Although several studies have produced anthropomorphic breast phantoms for X-ray imaging, the data available for MR imaging is still insufficient.⁸⁸⁻⁹⁵ Carton et al⁸⁸ used a computational model and a rapid prototyping technique to generate 3D breast phantoms with different compositions, sizes, and shapes made from tissue-equivalent materials for quality assessments of 2D and 3D breast X-ray imaging systems. The epoxy resins used in their study can simulate 100% of the characteristics of adipose tissue, while the FC-270 photopolymer simulates 50% of the properties of fibroglandular tissue.⁸⁸ Although this phantom effectively demonstrated a heterogeneous distribution of fibroglandular and adipose tissue that can be analogous to clinical breast images, it has certain limitations in terms of its fabrication method and applications: it is printed in slab form, which is overly complicated and time-consuming to manufacture on its actual format.⁸⁸

Mazzara et al⁸⁹ used the polysaccharide material TX-151 with water, sodium chloride (NaCl), and aluminium (Al) powder to create a tissue-mimicking material (TMM) in the form of a gel for constructing a realistic, inexpensive, easily mouldable, and temporally stable tissue-equivalent MRI breast phantom. The Al powder was used to decrease the T2 relaxation time, allowing the adaptation of the phantom to a wide range of relaxation times to simulate various human tissues and organs.⁸⁹ In addition, gadolinium-diethylenetriamine penta-acetic acid (Gd-DTPA), a paramagnetic metal complex, was used to adjust the T1 (and T2) relaxation times.⁸⁹

Liney et al⁹⁰ designed a simple and an inexpensive tissue-equivalent MRI breast phantom consisting of a layer of lard (a commercially available fat product) simulating adipose tissue, surrounded by a commercial jelly with varying concentrations simulating normal glandular tissue. Both of these phantoms can be used to conduct multipurpose quality assurance tests of such parameters as SNR, uniformity, and resolution, test the radio frequency coils, or examine various MRI diagnostic protocols.^{89, 90} Freed et al⁹¹ developed a tissue-equivalent phantom for quantitative assessments of breast MRI protocols using a combination of lard and egg whites to simulate adipose and glandular tissue, respectively. Although the materials successfully simulated the MR-related characteristics of T1 and T2 relaxation times of the tissues, they lack a heterogeneous structure and thus have minimal applicability for quantitative breast density assessment studies.⁹¹

Although some research has been conducted on the use of 3D printing techniques to develop breast phantoms for MRI, few studies have attempted to generate a personalized 3D-printed phantom based on breast MR images that can be similar to the anatomical structures of human tissues.⁸⁸⁻⁹⁵ Burfeindt et al⁹² reported a convenient

synthetic procedure to develop an MRI-derived 3D-printed phantom for preclinical use in microwave breast imaging experiments. Although it successfully simulated the dielectric properties of biological breast tissues, it was designed for microwave breast imaging rather than for MRI systems.⁹²

The importance of realistic phantom structures simulating the acoustic and optical breast tissue properties for the assessment of photoacoustic breast imaging systems was demonstrated by Dantuma et al.⁹³ In this study, a semi-anthropomorphic 3D-printed mould derived from an MRI segmented numerical breast model was developed using polyvinyl chloride plastisol (PVCP) to imitate real breast morphology.⁹³ However, there are limits to the extent to which a phantom designed for ultrasound and photoacoustic imaging can be used to simulate the MRI characteristics of breast tissues.⁹³ He et al⁹⁴ developed a 3D-printed breast phantom for machine calibration and image optimization in multi-modality imaging using a mixture of PVC powder and softener (dioctyl terephthalate) as a TMM. Although breast structures were successfully simulated, they lacked the appearance, variability, and heterogeneity of physiological tissue constructions.⁹⁴ Another potential limitation is that the materials' T1 and T2 relaxation times were found to be shorter than those reported in human breast tissues.^{94, 95}

2. Chapter 2

Quantitative Measurements of Breast Density Using

Magnetic Resonance Imaging: A Systematic Review and

Meta-Analysis

2.1 Abstract

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, is confirmed as an independent risk factor of breast cancer. Although there has been an increasing interest in the quantitative assessment of breast density, no research has investigated the optimal technical approach of breast MRI in this aspect. Therefore, we performed a systematic review and meta-analysis to analyze the current studies on quantitative assessment of breast density using MRI and to determine the most appropriate technical/operational protocol. Databases (PubMed, EMBASE, ScienceDirect, and Web of Science) were searched systematically for eligible studies. Single arm meta-analysis was conducted to determine quantitative values of MRI in breast density assessments. Combined means with their 95% confidence interval (CI) were calculated using a fixed- effect model. In addition, subgroup meta-analyses were performed with stratification by breast density segmentation/measurement method. Furthermore, alternative groupings based on statistical similarities were identified via a cluster analysis employing study means and standard deviations in a Nearest Neighbor/Single Linkage. A total of 38 studies matched the inclusion criteria for this systematic review. Twenty-one of these studies were judged to be eligible for meta-analysis. The results indicated, generally, high levels of heterogeneity between study means within groups and high levels of heterogeneity between study variances within groups. The studies in two main clusters identified by the cluster analysis were also subjected to meta-analyses. The review confirmed high levels of heterogeneity within the breast density studies, considered to be due mainly to the applications of MR breast-imaging protocols and the use of breast density segmentation/measurement methods. Further research should be performed to determine the most appropriate protocol and method for quantifying breast density using MRI.

Keywords Magnetic resonance imaging; breast density; fibroglandular-tissue; systematic review and meta-analysis; cluster analysis; segmentation; FCM; breast-imaging protocol; non-contrast- enhanced T1-weighted

2.2 Introduction

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, is an independent risk factor for breast cancer.¹⁻³ Consistent with this risk relationship, women who have dense breasts have a likelihood of developing breast cancer that is fourfold higher than those with fatty breasts.^{4,5} Most of the information regarding breast density has been acquired with two- dimensional imaging, which is mammography. However, the evaluation of breast density based on mammograms is limited due to the overlapping of tissues, variations in breast compression, and inappropriate positioning that lead to artefacts (skin folder) and inclusion of insufficient breast tissue.^{6,7} These factors could affect mammography's performance for precise, reliable measurements of small changes in breast density over brief timespans.^{8,9}

Magnetic resonance imaging (MRI), an alternative imaging modality in breast imaging can estimate the actual breast density value because it provides a three-dimensional volume assessment of breast tissue, with excellent contrast resolution in the differentiation between fibroglandular and fatty tissues.¹⁰⁻¹³ Conventionally, breast density is assessed qualitatively using the American College of Radiology (ACR) Breast Imaging-Reporting and Data System (BI-RADS) atlas, which is a classification system commonly used for mammography, according to which density has four categories based on the amount of fibroglandular tissue: “(1) almost entirely fat, (2) scattered fibroglandular tissue, (3) heterogeneous fibroglandular dense and (4)

extreme fibroglandular tissue”.^{14,15} The interpretations of these four categories are also applied for MRI. Despite its long clinical success, the BI-RADS scoring atlas is subjective and varies between readers, even within the same reader.¹⁶ To overcome a subjective assessment of breast density and to reduce inter- and intra- reader variability, different methods for quantitative breast density have been proposed, with a range of algorithms or methods reported in the literature.¹⁷⁻²² Each of these methods were shown to have advantages and limitations through the use of semi-automatic thresholding and segmentation approaches for quantitative assessment of breast density.

There is no doubt that MRI is one of the most useful modalities for breast imaging and that the analysis of breast density in quantitative synthesis is a well-established approach. In spite of the fact that extensive research has been carried out on breast density measurements, no consensus has been reached about the optimal approach to quantify breast density using MRI. Therefore, the purpose of this review is to analyze the current methods for the quantitative assessment of breast density using MRI over the past decade of publications. Due to the expected heterogeneity of MRI scanning protocols, both systematic review and meta-analysis were performed to analyze the available studies.

2.3 Materials and Methods

This systematic review and meta-analysis were performed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) criteria.^{23,24} No ethics committee approval was required.

2.3.1 Search Strategy and Eligibility Criteria

A systematic literature review was conducted of studies that analyzed breast density in a quantitative pattern using MRI. Briefly, a search for studies published between 1 January 2009 and 31 December 2018 was conducted in different databases: PubMed (MEDLINE, U.S. National Library of Medicine and National Institutes of Health, Bethesda, MD, USA), EMBASE (Elsevier, Amsterdam, The Netherlands), ScienceDirect (Elsevier, Amsterdam, The Netherlands), and Web of Science (Clarivate Analytics, Philadelphia, PA, USA) using the search terms detailed below.

Systematic search expressions were employed using MeSH (medical subject headings) in PubMed and the thesaurus in EMBASE, ScienceDirect, and Web of Science. A search structure was based on combining three main terms as follows: “breast density,” “quantitative analysis,” and “MRI.” The exact search expressions were “Breast Density” (MeSH term) OR “fibroglandular tissue” (Text word) OR “breast densit*” (Text word) OR “FGT” (Text word) OR “FT” (Text word) OR “fibroglandular densit*” (Text word) AND “Quantitative analysis” (Subject heading) AND “Magnetic Resonance Imaging” (MeSH term) OR “nuclear magnetic resonance imaging” (Text word) OR “MRI” (Text word) OR “magnetic resonance imaging” (Text word). The criteria for selecting the studies for eligibility were based on their title, abstract, and subsequently the full text, this was performed independently by two reviewers (R.S. and Z.S.). Studies addressing the quantitative analysis of breast density using MRI were considered eligible for inclusion and also studies on human subjects since 2009 had to be published in peer-reviewed journals and written in English. For study inclusion, the subjects must have undergone breast MRI studies and the breast density measurement method is known. Eligible studies were retrieved, and full manuscripts

were read. No restricted conditions have been applied in terms of study characteristics, the purpose of study, and the results. Publications were only included in the analysis if the measurement of breast density had been performed in a quantitative manner regardless of the MRI technique or breast density segmentation/measurement method.

2.3.2 Data Extraction

On completing the eligibility screening, the process of data extraction from the included studies was carried out manually by the same two reviewers. Descriptive data were extracted for all variables as follows: the first author's surname; year of publication; journal of publication; study type; total number of participants/patients; mean age; age range of participants/patients; MRI technique (pulse sequence/breast-imaging protocol and static magnetic field strength); and breast segmentation/measurement method. For each study analyzed, estimates of breast volume, fibroglandular-tissue volume and percentage breast density were recorded using descriptive statistics, arithmetic means and standard deviations, whenever appropriate. Due to the heterogeneous nature of this analysis, some of the included studies produced their results in a median and interquartile range (IQR). Accordingly, the researchers decided to stratify results and excluded them from the meta-analysis only.

2.3.3 Data Synthesis

The combinations of MRI techniques and the applied breast segmentation/measurement methods encountered in the studies were considered to be technologically heterogeneous. To address this issue and acquire more reasonable estimates, the analyses were stratified by breast segmentation method into three

discrete groups (fuzzy c-mean clustering (FCM), FCM and nonparametric nonuniformity normalization (N3), and signal intensity thresholding). In each sub meta-analysis, the number of the included studies were selected on the basis of a degree of homogeneity of their breast density segmentation/measurement results.

2.3.4 Statistical Analysis

The measurement of breast density as ascertained by MRI using semi- or fully-automated segmentation method was assessed. The primary outcome was the percentage breast density (%BD). Data input for each study within a group consisted of the study size (N), the ‘raw’ study mean (i.e., with no re-scaling or standardization), and the study standard deviation. The data was analyzed by the “metamean” function in the “meta” package in the R system, Version 3.4.1 (<http://www.r-project.org/>). This facilitates the meta-analysis of a single arm trial, as opposed to the traditional two arm trial with a control group and a treatment group, equivalent to a one-way analysis of variance. A forest plot was generated, displaying the individual study (%BD) means with 95% confidence interval (CI) limits, inverse variance study weights, and the pooled mean and confidence limits. Heterogeneity of study means was assessed using Cochran’s Q-test, and heterogeneity of study variances was assessed with Bartlett’s test. A conclusion to pool studies requires both heterogeneity tests to be non-significant at the 5% level.

As an alternative to grouping the studies on a technological basis, a cluster analysis was run to investigate any similarities between studies with respect to two attributes, namely study mean and study standard deviation. The International Business Machines Statistical Package for the Social Sciences (IBM SPSS) Statistics software Version 25.0 was used for cluster analysis. The procedure provides for a wide selection

of combinations of distance measures and clustering methods, but for the current application, the simplest of these was chosen, namely Euclidean distance and nearest neighbor agglomeration. This algorithm calculates a proximity matrix of distances between all possible pairs of studies and allocates the closest pair into a cluster, then examines the remaining clusters to identify which is the next nearest or whether there is a pair that are closer to one another, and so on.

2.4 Results

2.4.1 Literature Search

Figure 2.1 presents an overview of the systematic search of the literature through different databases. The complete search yielded 941 studies. After removing duplicates ($n = 70$), 871 were screened, based on their titles, which resulted in 765 being excluded, followed by 27 of the remaining studies being excluded on the basis of their abstracts. Of the remaining 79 studies, the full manuscript was retrieved and reviewed. Forty-one studies did not meet the selection inclusion criteria: no adequate breast density data ($n = 20$), qualitative analysis ($n = 12$), editorials ($n = 4$), conference abstracts ($n = 3$), post-mortem study ($n = 1$), and phantom study ($n = 1$). Finally, 38 studies attained the inclusion criteria^{1-3,5,11,25-57} and were included in the analysis as shown in Table 2.1.

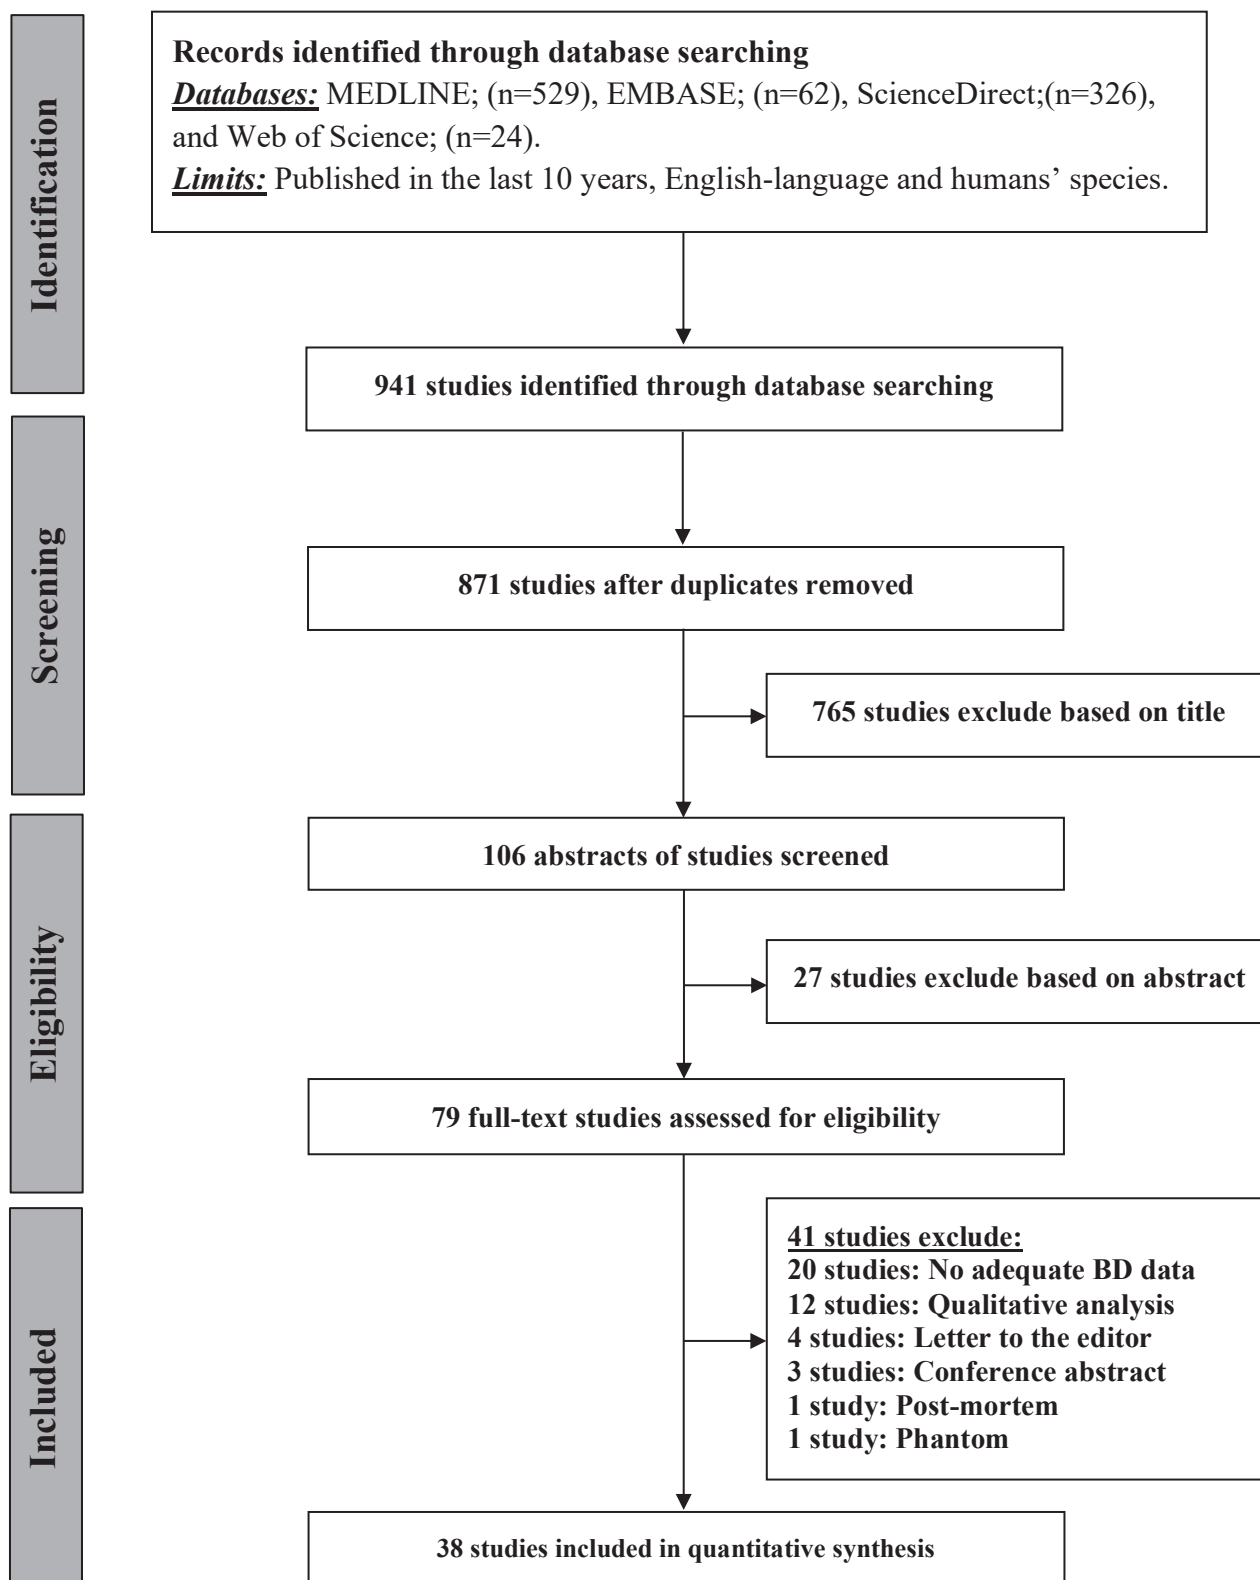

Figure 2.1. Preferred reporting items for systematic review and meta-analysis (PRISMA) flowchart of systematic review and meta-analysis of the excluded and included studies.

2.4.2 Systematic Search

Table 2.1 demonstrates some of the main characteristics of the 38 included studies, while Figure 2.2 shows details of the study design and MRI system used in these studies. Several MRI sequences were used to enable the precise differentiation between adipose and fibroglandular tissues; of these, non-contrast-enhanced T1-weighted was widely used either with 2D spin echo or 3D gradient echo. In fact, 16 studies (41.03%) used non-contrast-enhanced T1-weighted,^{1,2,26–29,31,33,35,44,45,48–51,53} while in 12 studies (30.77%) non-contrast-enhanced images were integrated with contrast-enhanced images.^{25,36–44,47,49} In terms of breast density segmentation/measurement, the majority of the studies (20 studies; 51.28%) used FCM clustering algorithm,^{1,2,11,25–29,31–42} while 7 studies (17.95%) used FCM and N3 algorithm,^{45–51} 4 studies (10.26%) interactive thresholding algorithm,^{3,5,52,53} 4 studies (10.26%) in-house customized software,^{29,53–55} one study (2.56%) manual software;⁵⁷ however, two studies did not provide the information.^{43,44}

Among the thirty-eight studies included in the systematic review and meta-analysis, 21 studies qualified for meta-analysis since they reported the percent breast density using an identical expression of measurement and dispersion (Table 2.1).^{1,3,11,25–32,36–38,45,48–50,53–55} However, for the remaining 17 studies, the percent breast density was reported in different format: in eight of these studies, it was defined as a median and interquartile range (IQR),^{2,39–44,47} and in the other nine, it was reported either in different measurement unit or the subject's sets were not independent, due to multiple usage.^{5,33–35,46,51,52,56,57} To perform the meta-analysis precisely, all the measured quantities should be reported in an identical expression of measurement and dispersion, thus we decided to exclude them from the meta-analysis.

2.4.3.1 Fuzzy C-mean Clustering (FCM)

The FCM subgroup consisted of 13 studies, of which, 10 studies reported breast density as a percentage breast density (% BD),^{1,11,25-32} whereas 3 studies as a percentage of the dense breast volume (% DBV).³⁶⁻³⁸ On one hand, 10 studies with inclusion of 634 patients were included, as Figure 2.3A shows, there is a wide range of mean values as well as standard deviation (SDs) from those studies, which indicated enormous heterogeneity among study means (Cochran's Q test: $X^2 = 86.93$, $P < 0.0001$). Indeed, there is a substantial heterogeneity among study variances (Bartlett's test: $X^2 = 110.59$, $P < 0.0001$). On the other hand, three studies with inclusion of 528 patients were analyzed. Figure 2.3B shows there is a high level of homogeneity among study means (Cochran's Q test: $X^2 = 0.13$, $P = 0.94$), and a high level of homogeneity among study variances (Bartlett's test: $X^2 = 0.12$, $P = 0.94$), which would be expected as those studies used an identical combination of MR technique and breast density segmentation/measurement approach.

2.4.3.2 FCM and Nonparametric Nonuniformity Normalization (N3)

The FCM and N3 subgroup included 4 studies with inclusion of 126 patients,^{45,48–50} as Figure 2.3C shows, there is a wide range of mean values as well as SDs from those studies, which indicated tremendous heterogeneity among study means (Cochran's Q test: $X^2 = 99.94$, $P < 0.0001$). Indeed, there is a substantial heterogeneity among study variances (Bartlett's test: $X^2 = 45.41$, $P < 0.0001$), which would be expected as those studies used different MR breast-imaging protocols.

2.4.3.3 Interactive Semi-Automated Threshold

Two studies^{3,54} comprising of 58 patients were included in the analysis, which indicated a considerable heterogeneity among study means (Cochran's Q test: $X^2 = 10.26$, $P = 0.0014$). In contrast, there was no evidence of heterogeneity among study variances (Bartlett's test: $X^2 = 1.61$, $P = 0.2072$). On the other hand, two studies with inclusion of 67 patients^{53,55} were analyzed as shown in Figure 2.3E, there was no evidence of heterogeneity among study means (Cochran's Q test: $X^2 = 3.01$, $P = 0.0825$), which would be expected as those studies used the same MRI technique and breast density measurement. However, there is a substantial heterogeneity among study variances (Bartlett's test: $X^2 = 18.84$, $P < 0.0001$).

2.4.4 Cluster Analysis

The results obtained from the clustering analysis "Dendrogram using Single Linkage" are shown in Figure 2.4. From this data, it can be seen that a hierarchical diagram showing various distances (0-25) at which studies joined various groups. On that basis, six clusters were identified. A list of cluster membership, study means, SDs, and CVs

(expressed as a percentage) is shown in Table 2.3. A scatter plot of the study means versus SDs is shown in Figure 2.5, the legend in the scatter plot indicates the number of studies in each cluster. Cluster markers with solid fill indicate clusters with two or more studies, whereas open markers indicate singletons. Cluster 1 included nine studies that analysed breast density with a combination of contrast and non-contrast T1-weighted either with 2D spin echo or 3D gradient echo; however, Choi et al⁴⁹ used diffusion-weighted scanning technique. From the data in Table 2.3, it is apparent that the CVs are varied in value, but in Choi's study⁴⁹ the CV is almost 100% because of the mean and SD are almost identical. In contrast, the CVs for Chan et al⁴⁸ and Chen et al⁵³ are much lower than the rest of the included studies, largely because of the small SDs and the breast segmentation methods being used which are FCM & N3 and interactive semi-automated threshold algorithms, respectively.

Tagliafico, 2014 [3]	-	-	-	-	48	55.00	23.20
Lodger, 2016 [54]	482.6	296.2	135.2	56.2	10	35.40	16.20
Chen, 2013 [53]	-	-	48.1 (ml)	24.7 (ml)	24	20.20	7.80
Wengert, 2015 [55]	1462.43	803.38	-	-	43	26.05	19.47

In contrast, cluster 2 consisted of 8 studies that assessed breast density with a combination of contrast- and non-contrast-enhanced T1-weighted with 3D gradient echo, however, Chen et al³¹ and Chen et al⁴⁵ used non-contrast- and contrast-enhanced T1-weighted with 2D spin-echo, respectively. Indeed, Chen et al⁴⁵ analyzed breast density using FCM and N3 algorithms. From the data in Figure 2.5 and Table 2.3 (Cluster 2), it is apparent that the CVs are almost within a closed range except for Chen et al⁴⁵ where the CV is much lower than the remaining studies because of the small SD and the breast segmentation method that previously mentioned. Also, Wengert et al⁵⁵ used Dixon method as a technical protocol for breast-imaging, although they measured the breast density using in-house customized software, the mean and SD are not different to the other included studies. The most striking result to emerge from the data in Figure 2.5 and Table 2.3 (Cluster 3–6) is the Chen et al¹ study (i.e., Cluster 3), although it used non-contrast-enhanced T1-weighted with 3D gradient echo and analyzed breast density by FCM algorithm, the CV (11.67%) is much lower than the remaining studies, mainly because of the small SD.

Cluster 4 included two studies Chan et al⁴⁸ and Chen et al⁵⁰ that assessed breast density using FCM and N3 algorithms and non-contrast-enhanced T1-weighted with 3D gradient echo. As can be seen from the data in Figure 2.5 and Table 2.3 (Cluster 3–6) the study means and SDs are not different. In contrast to this Cluster 5, the Tagliafico et al³ study used 3D contrast-enhanced T1-weighted gradient echo sequence and analyzed the breast density by semi-automated interactive threshold, in particular, (MedDensity). As Figure 2.5 and Table 2.3 (Cluster 3–6) show, the study mean is much higher than the remaining studies, largely because of the technical method used. Finally, cluster 6 consisted of Lodger et al,⁵⁴ this is the only study that used proton

density weighted sequence. Detailed information of clustering membership, study means, SDs, and CVs is shown in Table 2.3, Figures 2.4 and 2.5.

Switching from technology groupings of studies to groupings identified by the cluster analysis, meta-analysis of cluster 1 revealed that the study means, and study variances are both heterogeneous (Cochran's test for heterogeneity of study means, $X^2 = 22.26$, $P = 0.0045$, and Bartlett's test for heterogeneity of study variances, $X^2 = 21.47$, $P = 0.0060$, see Figure 2.6A). When Choi et al⁴⁹ was excluded (because of the very large CV), the cluster has improved somewhat, which would be expected as this study used different protocols (i.e. diffusion-weighted imaging). It can be seen from the data in Figure 2.6B that the study variances are no longer heterogeneous ($X^2 = 8.84$, $P = 0.2641$), although the study means remain heterogeneous ($X^2 = 19.54$, $P = 0.0066$). In contrast, meta-analysis of cluster 2 indicated that the study means are not heterogeneous ($X^2 = 4.77$, $P = 0.6874$), while the study variances are mildly heterogeneous ($X^2 = 15.54$, $P = 0.0206$, see Figure 2.7).

2.5 Discussion

The present systematic review and meta-analysis was performed to analyze the current studies on quantitative breast density using MRI and to determine the most appropriate technical/operational protocol. Through reviewing 38 studies from the literature, despite many methods and protocols available, no gold standard has been established with a wide range of heterogeneous methods or protocols used in these studies. To the best of our knowledge, this is the first comprehensive systematic review and meta-analysis of pooling the results of all breast density segmentation/measurement methods using MRI data. The analysis indicated that the non-contrast-enhanced T1-weighted acquisition was commonly utilized among all MR breast-imaging protocols. Another important finding of this analysis was that the FCM is the most frequently used algorithm amongst the breast density segmentation/measurement methods. Also, the results showed that a high level of heterogeneity was mainly associated with the breast-imaging protocols and the breast density segmentation/measurement methods.

Further attempts have been made by using clustering methods and meta-analysis to identify groups of studies which are as homogeneous as possible within groups and as heterogeneous as possible between groups. The included studies were grouped together into clusters based on their nearest neighbor Euclidean distances. On that basis, clusters 1 and 2 were considered as the most valuable results. Briefly, cluster 1 consisted of 9 studies,^{25-30,48,49,53} as shown from the data in Table 2.3 and Figure 2.6A that the CVs are varied in value, but in Choi et al⁴⁹ the CV is almost 100% because of the mean and SD are almost identical. This result may be explained by the fact that among the 8 studies,^{11,31,32,36-38,45,55} the breast-imaging protocol was a combination of contrast- and non-contrast-enhanced T1-weighted either with 2D spin echo or 3D

gradient echo, while in Choi et al⁴⁹ the MRI protocol used was diffusion-weighted imaging. Consequently, it is advisable to exclude it from the meta-analysis to reduce the heterogeneity within cluster 1. Consistent with this hypothesis, the results have improved in somewhat, even though the study variances are not heterogeneous ($P > 0.05$), the study means are heterogeneous ($P < 0.05$) (Figure 2.6B). Although exclusion of Choi et al⁴⁹ did not reduce the heterogeneity, these results should be interpreted with caution. The discrepancy could be largely attributed to that although the MR breast-imaging protocols are not dissimilar (i.e., contrast- and non-contrast-enhanced T1-weighted), the breast segmentation/measurement methods are vice versa (i.e., FCM, FCM and N3, and in-house customized software). In contrast, cluster 2 included 8 studies, in 3 of these studies the breast density was reported as a (%DBV), while the remaining as a (% BD). Among these studies, the contrast- and non-contrast-enhanced T1-weighted was often used. From the data in Table 2.3 and Figure 2.7, it is apparent that the study means are not dissimilar ($P > 0.05$), although the study variances are heterogeneous ($P < 0.05$). Among the 21 studies included in the cluster analysis, although the fixed effect meta-analysis of cluster 2 has improved slightly, the heterogeneity within group still exist. There are two likely causes for this heterogeneity: the applied MR breast-imaging protocol and the used breast density segmentation/measurement methods.

Although the study has successfully confirmed the variation in the breast density segmentation/measurement methods using MRI data, the findings are subject to several limitations. First, the heterogeneity of study aims, the study design utilized, and the technical/operational methods applied, for instance, the MR breast-imaging protocol, MR scanner manufacturer, and the static magnetic field strength present challenges for performing the meta-analysis. Second, the breast density

segmentation/measurement algorithm used is another limitation. Although we classified the included studies into discrete subgroups (i.e., FCM, FCM and N3, and interactive semi-automated threshold), and applied stratified analyses, the heterogeneity remains. Third, the definition of the breast density was inconsistent because some studies reported it as a percentage of dense breast volume, while the others as a percentage of breast density. Fourth, among the 38 studies included in this analysis, only 21 studies were eligible for meta-analysis due to the statistical requirements for the input values that should be in identical expression of measurement and dispersion. In addition, some of the included studies used the same set of the subject multiple times for different purpose and feature. Even though we decided to rectify the issue by selecting one of the results of data at random, or by any meaningful clinical criterion, the heterogeneity continues to exist. Notwithstanding these limitations, the study further supports the idea of developing a standard MRI protocol for the quantitative assessment of breast density.

Future research can be suggested according to findings of this review. A recent study has reported the feasibility of creating a realistic 3D printed breast phantom for quality control purpose.⁵⁸ Thus, we consider 3D printing technique can be used to develop a patient-specific 3D printed breast phantom with different amounts of breast composition to quantify the volume of FGT. Further, the 3D printed model can be used to examine several MR breast-imaging protocols not only to measure the breast density but also to assess the impact of implementing various image quality parameters (i.e., FOV, matrix size and slice thickness) on the segmentation/measurement of breast density. Finally, the accuracy of different breast density/FGT segmentation methods can be determined.

2.6 Conclusion

This systematic review and meta-analysis confirms and substantiates the variation among the breast density segmentation/measurement methods using MRI. Furthermore, subgroup meta-analyses and further clustering methods indicated that a significant heterogeneity within and between groups exist. The analysis confirmed that the non-contrast-enhanced T1-weighted acquisition was commonly utilized among all MR breast-imaging protocols and the FCM is the most frequently used algorithm amongst the breast density segmentation/measurement methods. Future work will need to determine the most appropriate protocol and method for quantifying breast density using MRI.

3. Chapter 3

Development of Patient-Specific 3D-Printed Breast

Phantom Using Silicone and Peanut Oils for Magnetic

Resonance Imaging

3.1 Abstract

Background: Despite increasing reports of 3D printing in medical applications, the use of 3D printing in breast imaging is limited, thus, personalized 3D-printed breast model could be a novel approach to overcome current limitations in utilizing breast magnetic resonance imaging (MRI) for quantitative assessment of breast density.

Purpose: The aim of this study is to develop a patient-specific 3D-printed breast phantom and to identify the most appropriate materials for simulating the MR imaging characteristics of fibroglandular and adipose tissues. **Methods:** A patient-specific 3D-printed breast model was generated using 3D-printing techniques for the construction of the hollow skin and fibroglandular region shells. Then, the T1 relaxation times of the five selected materials (agarose gel, silicone rubber with/without fish oil, silicone oil, and peanut oil) were measured on a 3T MRI system to determine the appropriate ones to represent the MR imaging characteristics of fibroglandular and adipose tissues. Results were then compared to the reference values of T1 relaxation times of the corresponding tissues: $1,324.42 \pm 167.63$ and 449.27 ± 26.09 ms, respectively. Finally, the materials that matched the T1 relaxation times of the respective tissues were used to fill the 3D-printed hollow breast shells. **Results:** The silicone and peanut oils were found to closely resemble the T1 relaxation times and imaging characteristics of these two tissues, which are $1,515.8 \pm 105.5$ and 405.4 ± 15.1 ms, respectively. The agarose gel with different concentrations, ranging from 0.5 to 2.5 wt%, was found to have the longest T1 relaxation times. **Conclusions:** A patient-specific 3D-printed breast phantom was successfully designed and constructed using silicone and peanut oils to simulate the MR imaging characteristics of fibroglandular and adipose tissues. The phantom can be used to investigate different MR breast imaging protocols for the quantitative assessment of breast density.

3.2 Introduction

Breast magnetic resonance imaging (MRI) is a well- established approach in the diagnosis of breast disease, and it has become an important modality in the screening of women at high-risk of breast cancer, preoperative staging of newly diagnosed breast cancer, and follow-up of breast cancer treatment.¹⁻³ Hence, the European Society of Breast Imaging (EUSOBI) has recommended that breast MRI be used as an adjuvant modality in women at high- risk of developing breast cancer,³ for those with (BRCA-positive genetic mutation carriers), family history, and/or high breast density.⁴

Breast density, a measure of fibroglandular, dense tissue relative to fatty, non-dense tissue, is an independent risk factor of breast cancer.⁵⁻⁷ Consistent with this risk relationship, women who have dense breasts have a likelihood of developing breast cancer that is fourfold higher than those with fatty breasts.^{8,9} Currently various methods have been developed and introduced to segment/ measure breast density using MRI: the utilization of a clustering algorithm, the segmentation of glandular and fatty tissues with an interactive thresholding algorithm, a logistic function approach and a curve-fitting algorithm; each has its advantages and limitations.¹⁰⁻¹⁴ However, there are certain drawbacks associated with the use of these algorithms as most of them are interpreted as measurements with a semi-automatic thresholding and segmentation methods. Likewise, different MR breast- imaging protocols have been used to differentiate between adipose and fibroglandular tissues ranging from non- contrast-

enhanced T1-weighted to contrast-enhanced T1-weighted and diffusion-weighted acquisitions.¹⁵⁻¹⁹ Despite improvements in the quantitative assessment of breast density using MR imaging, there has been no general agreement about the optimal scanning protocol in this aspect. A recent systematic review and meta-analysis about the quantitative assessment of breast density has confirmed these variations among breast segmentation/measurement methods and MR breast-imaging protocols.²⁰

In recent years, there has been an increasing interest in 3D printing techniques, which are being used in different medical domains such as cardiovascular disease, orthopaedic surgery, prosthetics, and neurosurgery.²¹⁻²⁴ 3D-printed models have been shown to assist in the development of many surgical implants, which can improve the individual's understanding of such a complex anatomical structure.²¹ Several studies have produced anthropomorphic breast phantoms for X-ray imaging, but there is still insufficient data available for MR imaging.²⁵⁻³⁰ Carton et al²⁵ developed a 3D anthropomorphic breast phantom for the evaluation of image quality of 2D and 3D breast X-ray imaging systems. This phantom was based on a computational model and a rapid prototyping technique to generate breast phantom with different compositions, sizes, and shapes by using a tissue-equivalent material.²⁵ While the phantom has effectively demonstrated a heterogeneous distribution of the fibroglandular and adipose tissues that can be analogous to the clinical breast images, it has certain limitations in terms of its fabrication method and application. The phantom has been printed in slabs form, which is very complicated to manufacture and it is a time-consuming process.²⁵

Although some research has been carried out on the use of 3D printing techniques to develop a breast phantom for MR imaging, only few studies have attempted to

generate a personalized 3D-printed breast phantom based on a realistic breast MR images that can be similar to the anatomical structures seen in human tissues.²⁶⁻³⁰ Burfeindt et al²⁶ reported a new and convenient synthetic procedure to develop an MRI-derived 3D-printed breast phantom for the preclinical use in microwave breast-imaging experiments. Although the phantom has successfully simulated the dielectric properties of the biological breast tissues, it has been designed for microwave breast-imaging rather than for MR imaging system.²⁶ Furthermore, the importance of realistic phantom structure in the assessment of photoacoustic breast imaging systems for the purpose of simulating the acoustic and optical breast tissues properties was demonstrated in a study by Dantuma et al,²⁷ in which a semi-anthropomorphic 3D-printed moulds derived from a MRI segmented numerical breast model was developed to produce real breast morphology using polyvinyl chloride plastisol (PVCP). However, there are limits to how far the phantom that has been designed for ultrasound and photoacoustic imaging can be used to simulate the MR imaging characteristics of breast tissues.²⁷ Moreover, He et al²⁸ developed a 3D-printed breast phantom for machine calibration and image optimization in multi-modalities imaging, where a mixture of PVC powder and softener (i.e., dioctyl terephthalate) was used as a tissue-mimicking material (TMM) of breast tissues.

Although the study has successful demonstrated the simulation of breast structures, it has certain limitations in terms of the lack of the appearance, variability, and heterogeneity of structures that are presented in the physiological tissues.²⁸ Another potential limitation is that the T1 and T2 relaxation times of the materials were measured and found to be shorter than those reported in the physiological human breast tissues.^{28,29} While most of the aforementioned phantoms address their objectives in the medical imaging discipline, there are currently no phantoms available to evaluate

the breast density based on a realistic morphology of breast structures derived from a MR images of human tissues. Likewise, uncertainties still exist about the most appropriate TMMs that can be used to simulate the MR- related characteristics and appearance of breast structures, particularly fibroglandular tissue. Such a personalized 3D-printed breast model could be used to examine different MR breast-imaging protocols not only to evaluate the breast density but also to determine the impact of applying various image quality parameters on the segmentation/ measurement methods of breast density. Therefore, the aim of this study is to develop a patient-specific 3D-printed breast phantom and to identify the most appropriate materials for simulating the MR imaging characteristics of fibroglandular and adipose tissues.

3.3 Methods

3.3.1 Patient Data

Ethical approval was obtained from Curtin University's Human Research Ethics Committee (HREC) and King Fahd Armed Forces Hospital's (Jeddah) Research and Ethics Committee. A random sample of patients with no history of breast disease was retrospectively reviewed from an existing breast MRI database. The criteria for selecting the subjects were the following: no previous surgery, no radiotherapy treatment on the chest wall, no history of breast cancer, and a Breast Imaging-Reporting and Data System (BI-RADS) classification of 1, indicating a negative likelihood of cancer. A 46-year-old woman was identified by a senior radiology resident to match the selection criteria. The breast MRI examination was performed using 1.5T system (MAGNETOM Aera, Siemens, Germany) with a dedicated breast coil (18 channels). The MR breast imaging protocol was chosen based on the recommendations of a recent systematic review and meta-analysis²⁰ as high-resolution

non-contrast-enhanced T1-weighted images to allow a precise differentiation between adipose and fibroglandular tissues: TR/TE 11.8/6.0 ms; matrix size 384×384; slice thickness 0.9 mm with no gap.

3.3.2 Image Post-processing and Segmentation Process

A series of image post-processing and segmentation of the volumetric data was performed. First, the anonymized Digital Imaging and Communications in Medicine (DICOM) MR images were imported into the commercially available software Analyze 12.0 (AnalyzeDirect, Inc., Lexana, KS, USA) to segment the non-contrast-enhanced T1-weighted breast images. Second, the breast's boundary was delineated manually to distinguish the breast's body from the surrounding tissues (pectoral muscle, heart, lungs, and thorax) on each 2D slice based on grayscale intensity, displayed in a histogram. Then, the 3D breast volume was created by these 2D images and was subsequently used to design the 3D-printed breast model. Finally, the 3D segmented MR breast volume was saved as a standard tessellation language (STL) file for further image post-processing and 3D printing. Figure 3.1 presents a schematic flowchart of the process of developing a patient-specific 3D-printed breast model using MRI data. For more details, the phantom consists of three main parts: the outer shell, simulating the skin layer, and the internal structures, which include fibroglandular and fat tissues, imitating the breast composition. To generate the skin shell, the STL file containing the 3D segmented MR breast volume was imported into the Blender software, version 2.79b (Blender Foundation, Amsterdam, Netherlands) to hollow the model and ensure that all the internal structures were perfectly extracted. On the other hand, the DICOM MR breast dataset was loaded into the 3D Slicer software, version 4.10.2 [National Alliance for Medical Image Computing (NA-MIC)]

to segment out the fibroglandular tissue and ensure that all the surrounding structures were completely removed. To increase reliability of the segmentation, each slice was segmented in different orientations using the threshold function, which was adjusted manually. This approach was used to threshold the DICOM dataset so that only the fibroglandular tissue structures were kept in the final segmented data. Subsequently, the segmented fibroglandular model was saved as a STL file and imported into the (version 3.5.474, Autodesk Inc., San Rafael, CA, USA) open-source software for further edit. Any deformities or free-floating objects were removed, and any holes were fixed during the editing process.

Figure 3.1. Schematic flowchart demonstrates the process of developing a patient-specific 3D-printed breast model.

3.3.3 Overview and Breast Phantom Design

This part is divided into three sections, each detailing the construction process related to the 3D-printed breast model components.

3.3.3.1 Skin Layer

Based on the dimensions of a realistic tissue, the outer phantom shell had an average thickness of 3.0 mm, which corresponds to the normal skin thickness. The cover of the skin shell was designed using a computer-aided design (CAD) software. The skin shell and the cover were fabricated with fused deposition modelling (FDM) technology using polylactic acid (PLA) (Polymaker, Shanghai, China) on a Raise3D N2 Plus 3D printer (Raise3D, Irvine, CA, USA). The skin shell was printed with a layer height of 0.15 mm, average printing time of 40 hours, and a resolution of 12.5 μm (Figure 3.2).

Figure 3.2. External structure of the patient-specific 3D-printed breast phantom that consists of 3 mm thick skin layer and compartments to be filled with fibroglandular and adipose tissues models.

3.3.3.2 Fibroglandular Region

The fibroglandular models constitute the internal component of the 3D-printed breast phantom. While various definitions of the term “breast density” have been proposed, in this study, the term “fibroglandular tissue” is used to refer to the breast density. Naturally, the fibroglandular region contains variable shapes and/or volumes of glandular tissue, includes fibrous or connective tissue. In clinical practice, the evaluation of fibroglandular tissue is based on a subjective assessment recommended by the American College of Radiology (ACR) BI-RADS, which is commonly used for

mammography but also for MRI. The BI-RADS atlas can be described as a classification system that characterises breast density on the basis of the amount of fibroglandular tissue into four categories: (I) almost entirely fat, (II) scattered fibroglandular tissue, (III) heterogeneous fibroglandular tissue, and (IV) extreme fibroglandular tissue.^{31,32}

In order to simulate the MR imaging characteristics, the 3D fibroglandular models were designed as hollow structures with an average thickness of 2.0 mm. The fibroglandular models were fabricated using the digital light processing (DLP) technology on an Anycubic Photon S 3D DLP UV resin printer (Shenzhen Anycubic Technology Co. Ltd., Shenzhen, China) using white photopolymer resin (Magma H LINE Photopolymer Resin) from Magma Filament, Malaysia. A curing time of 10 sec per layer, a layer thickness of 0.05 mm, and a resolution of 47 μm were used to fabricate the fibroglandular models. The printing duration for both left and right fibroglandular models was about 17 hours (Figure 3.3).

Figure 3.3. Fabrication of the hollow fibroglandular models using the Anycubic photon S high-resolution 3D DLP UV resin printer. The thickness of the wall is 2.0 mm. DLP, digital light processing.

3.3.3.3 Fat/Adipose Region

This region comprises a considerable part of the 3D-printed breast model. It consists of a selected material that simulates the MR imaging relaxation times of adipose tissue.

3.3.3.4 Fibroglandular TMMs

Agarose gels with different concentrations vary in their ability to simulate the MR imaging characteristics of T1 and T2 relaxation times of an extensive range of human tissues.^{33,34} In a study investigating the T1 and T2 relaxation times of four sample phantom liquids, Gach et al³³ found that silicone oil had the longest T1 and T2 times on a 3T MRI system: $1,068.29 \pm 5.95$ and 566.40 ± 4.68 ms, respectively. These results provide further support to the hypothesis that agarose gel or silicone oil could be used to mimic the MR imaging characteristics of fibroglandular tissue based on T1 and/or T2 relaxation times. Thus, four different raw materials were scanned to determine which one could be used to mimic the T1 and/or T2 relaxation times of fibroglandular tissue. The candidate materials were silicone oil with a viscosity of $50 \text{ mm}^2/\text{s}$ at $25 \text{ }^\circ\text{C}$ (TEX Chemical Inc., Country), agarose (Thermo Fisher, Waltham, MA, USA), silicone rubber RTV (Craftiviti Sdn. Bhd., Selangor, Malaysia), and fish oil (Blackmores, Sydney, Australia) (Figure 3.4).

3.3.3.5 Fat/Adipose TMMs

As Niebuhr et al³⁵ reported, olive oil successfully simulates the MR imaging relaxation times of adipose tissue in abdominal and pelvic tissues measured *in-vivo*. In another study, Niebuhr et al³⁴ found that peanut oil efficiently simulates the MR imaging characteristics of subcutaneous fat for pelvis phantoms. Peanut oil was preferred in this study for several reasons, including its relatively similar MR imaging

characteristics (T1 and T2 relaxation times) for adipose tissue, its translucent appearance, and its high oxidation stability.^{34,35} These characteristics suggest that peanut oil could be a performed material to mimic the T1 and/or T2 relaxation times of breast adipose tissue. Two types of peanut oil were scanned for testing: peanut oil Basso (raw material: *Arachis hypogea*; price: US\$ 5/1L; Basso), and peanut oil Pressed Purity (raw materials: oleic acid (96.2%) and linoleic acid (13.2%), price: US\$18/1.5L, Proteco Oils) (Figure 3.4).

3.3.4 Breast Phantom Construction

The T1 relaxation times of the five selected materials (agarose gel, silicone rubber with/without fish oil, silicone oil, and peanut oil) were measured at room temperature using a 3T MRI system to determine which ones could be used to mimic the MR imaging characteristics of fibroglandular and adipose tissues. The results were then compared to the reference values of T1 relaxation times of the corresponding tissues. Following this, the materials that matched the T1 relaxation times of the respective tissues were chosen to fill the 3D-printed hollow breast shells.

Figure 3.4. Test raw materials. (A) Silicone rubber; (B) silicone rubber with fish oil; (C) fresh silicone rubber; (D) silicone oil with a viscosity of 50 mm²/s; (E) peanut oil (basso); (F) peanut oil (pressed purity); (G) agarose gel 0.5 wt%; (H) agarose gel 1.0 wt%; (I) agarose gel 1.5 wt%; (J) agarose gel 2.0 wt%; (K) agarose gel 2.5 wt%.

3.4 Results

3.4.1 3D-printed Hollow Models

The 3D-printed models of the hollow skin and fibroglandular region shells were scanned on a 3T MRI system (MAGNETOM Prisma, Siemens Healthcare, Erlangen, Germany) to check whether the models printed with the PLA or the photopolymer resin produce MR signals corresponding with these tissue features. Fortunately, no MR signal was observed from scanning the 3D-printed hollow models, indicating the possibility of using these materials for breast structure simulation and further patient models. It is important to note that the selected materials were checked when the 3D printing was initially performed and then checked again at the end of the breast phantom construction.

3.4.2 Sample Characteristics

The five selected materials were scanned on the same 3T MRI system, with the materials placed in the 18-channel body and 32-channel spine coils. The MR breast scanning was chosen based on the institutional clinical protocol using 3D T1- and T2-weighted turbo spin echo (TSE) sequences: TR/TE 650.0/10.0 ms; matrix size 384×384; slice thickness 2.9 mm; no gap, and TR/TE 6,080.0/78.0 ms; matrix size 384×384; slice thickness 4.0 mm; no gap, respectively.

Figure 3.5 presents the MR imaging T1 relaxation times of the five materials (agarose gel, silicone rubber with/without fish oil, silicone oil, and peanut oil) simulating the breast composition. Figure 3.5D shows that the T1-weighted image of the silicone oil was associated with a mid-grey signal intensity, which is usually related to water-based tissues characterized by a moderate T1 relaxation time. On the other hand, Figure

3.5E,F shows that the T1-weighted images of the peanut oils indicated a high signal intensity, which was within expectation, as fat-based tissues have a short T1 relaxation time. In contrast, the T1-weighted images of the agarose gel with different concentrations, 0.5 to 2.5 wt%; were associated with low signal intensity, which is mainly observed in free water and other fluids (Figure 3.5G,H,I,J,K).

Figure 3.5. T1-weighted images. (A) Silicone rubber; (B) silicone rubber with fish oil; (C) fresh silicone rubber; (D) silicone oil with a viscosity of 50 mm²/s; (E) peanut oil (basso); (F) peanut oil (pressed purity); (G) agarose gel 0.5 wt%; (H) agarose gel 1.0 wt%; (I) agarose gel 1.5 wt%; (J) agarose gel 2.0 wt%; (K) agarose gel 2.5 wt%.

3.4.3 T1 Relaxation Times of the Sample Characteristics

The T1 relaxation times of these five materials are listed in Table 3.1. Silicone oil had a T1 relaxation time similar to that of fibroglandular tissue: 1,515.8±105.5 ms. In contrast, the Basso and Pressed Purity peanut oils had T1 relaxation times analogous to that of adipose tissue: 405.4±15.1 and 404.1±10.5 ms, respectively. For comparison, the T1 and T2 relaxation times of fibroglandular and adipose tissues measured using a 1.5T and a 3T MRI system are presented in Table 3.2.

As shown in Table 3.1, the agarose gel with different concentrations, ranging from 0.5 to 2.5 wt%, had the longest T1 relaxation times, which are similar to that of free water. The interesting finding is that the lowest concentration was associated with the highest

T1 relaxation time. Overall, the results presented in Table 3.1 and Figure 3.5 indicate that the silicone and peanut oils closely resemble the MR imaging T1 relaxation times of the fibroglandular and adipose tissues, respectively. Therefore, these materials were chosen to fill the 3D-printed hollow models.

Figure 3.6 provides an overview of the construction process of the 3D-printed breast phantom. The two fibroglandular shell models were filled with a silicone oil and then sealed using UV-curable photopolymer resin. Following this, the filled fibroglandular shell models were fixed inside the skin shell model using acrylic-based adhesive. Further, the space between the fibroglandular and skin shell models was filled with peanut oil. A home-made silicone gasket and cover were used to enclose the breast phantom. Finally, the cover was tightened using the commercially available polycarbonate bolt and nuts.

Table 3.1. T1 Relaxation times of different materials for tissue surrogates used in the experiment.

Phantom, TMM	T1 (average SD, ms), 3T Siemens MR Scanner
Fibroglandular shell	No signal
Skin/outer shell	No signal
Silicone rubber	577.2 ± 107.8
Silicone rubber with fish oil	902.1 ± 120.5
Fresh Silicone rubber	638.3 ± 108.5
Silicone oil 50 mm ² /s *	1515.8 ± 105.5
Peanut oil (Basso)	405.4 ± 15.1
Peanut Oil (Pressed Purity)	404.1 ± 10.5
Agarose gel 0.5 wt%	4015.5 ± 100.2
Agarose gel 1.0 wt%	3877.8 ± 130.5
Agarose gel 1.5 wt%	3404.8 ± 255.9
Agarose gel 2.0 wt%	3572.6 ± 100.4
Agarose gel 2.5 wt%	3617.2 ± 101.5

Figure 3.6. Flow chart showing 3D construction of the breast phantom. 3D-printing technique was used to create the hollow shells for skin and fibroglandular regions. Fibroglandular and adipose tissues were simulated using silicone and peanut oils, respectively.

3.4.4 Scanning of the 3D-printed Breast Phantom

The MR images of the phantom were acquired following the same breast imaging protocols described in the Results, Sample Characteristics. The phantom was scanned in a prone position using a dedicated 18-channel breast coil. Figure 3.7 shows the T1- and T2-weighted MR images of a patient-specific 3D-printed breast phantom using silicone and peanut oils as surrogates of the fibroglandular and adipose tissues, respectively. These oils presented an acceptable level of contrast and MR-related characteristics in both the T1- and the T2-weighted images. One of the most noticeable features of this phantom is that it is slightly inhomogeneous. However, this feature simulates the considerable inhomogeneity as often observed among the irregular distribution of the patient. Overall, the results shown in Table 3.1 and Figure 3.5 indicate that the MR imaging T1 relaxation times of the silicone and peanut oils used for the simulation of fibroglandular and adipose tissues are similar to their respective reference values reported in the literature.

Figure 3.7. MR images of the 3D-printed breast phantom. (A) T1-weighted image; (B) T2-weighted image using TSE scans. TSE, turbo spin echo.

3.5 Discussion

This study aimed to develop a patient-specific 3D-printed breast phantom and to determine the most appropriate materials for simulating the MR imaging characteristics of fibroglandular and adipose tissues. Anthropomorphic shapes of skin and fibroglandular tissues were constructed using 3D-printing techniques based on the segmentations of breast MR images from a selected healthy patient's data. All the 3D skin and fibroglandular region shells were designed as hollow structures using PLA and photopolymer resin. Since no MR signal was generated by the 3D-printed hollow models of those corresponding shells, different materials were selected to search for suitable ones with silicone oil and peanut oil being the most appropriate materials with similar T1 relaxation times to fibroglandular and adipose tissues.

It was assumed that the T1 relaxation times would effectively supplement and extend our knowledge about the selected materials since most organs' T1 values are five times longer than their T2 values. A comparison of the T1 relaxation times of the scanned materials with breast structure and literature reports showed that the silicone and peanut oils closely resemble the MR imaging T1 relaxation times of the fibroglandular and adipose tissues, respectively. Surprisingly, this study did not find a significant difference in the T1 relaxation times between different concentrations of agarose gel, which exhibited long T1 relaxation times, similar to that of water. Nevertheless, the agarose gel can be mixed with a gadolinium-based contrast agent for T1 adaptation, and can thus be used to simulate the MR imaging relaxation times of a wide range of human tissues. However, this would be costly and requires precautions when handling the contrast agent. Another unexpected finding was the slight difference in the T1 relaxation times between the Basso and Pressed Purity peanut oils. However, the

observed difference was not significant. It is also worth noting that the Basso peanut oil was preferable due to its purity, availability, and low cost.

The most important clinically relevant finding was that the silicone and peanut oils demonstrated an acceptable level of contrast and MR-related characteristics of breast structures in both the T1- and the T2-weighted images. These findings are in line with Niebuhr et al,³⁴ who suggested that peanut oil efficiently simulates the MR imaging characteristics of subcutaneous fat for pelvis phantoms. In accordance with the present results, previous studies demonstrated that silicone oil with a viscosity of 50 mm²/s had the longest T1 and T2 relaxation times on a 3T MRI system.^{33,35} However, silicone oil was not previously used for simulating the MR-related characteristics of breast structures, particularly fibroglandular tissue. Thus, this study presents interesting findings to encourage more research along this direction in breast phantom.

The observed correlation between silicone oil's T1 relaxation time and fibroglandular tissue could be attributed to its chemical composition and physical properties such as viscosity and density. This preliminary finding: suggests that silicone and peanut oils can be used to efficiently simulate the MR imaging characteristics of breast structures and produce further models. An implication of this is the possibility to examine different MR breast imaging protocols to identify the most appropriate for the quantitative assessment of breast density. For future investigations, it might be possible to use different chemical compositions and physical properties of silicone oils to evaluate the MR imaging relaxation times of breast structures. Since the relationship between silicone oil and fibroglandular tissue has not been studied, further research is required to better understand it.

Although the study has successfully designed and constructed a patient-specific 3D-printed breast phantom, the findings are subject to several limitations. The study was not specifically designed to evaluate the mechanical properties of breast tissue components, such as elastic modulus or tissue strength. Examining the mechanical features along with the physical properties of selected materials could provide an idea of their characteristics and allow more detailed comparisons to the human breast tissue. Moreover, there are certain drawbacks to the use of 3D printing techniques for the construction of skin and fibroglandular hollow shells. One of them is the potential risk for some of the connected structures to break easily during the cleaning process. For this reason, several models of varying wall thicknesses, ranging between 1.0 and 2.5 mm, were printed. However, increasing the thickness of photopolymer resin can cause considerable deformation of the fibroglandular structure. Another potential limitation is due to the complexity of the fibroglandular structure, with holes formed in the final mould. For this reason, a wrapping process was performed manually for each model to ensure that all the small gaps had been completely sealed.

A further study on a patient-specific 3D-printed breast phantom will be conducted with a focus on different percentages of fibroglandular tissue. This can correspond to the four categories of the ACR BI-RADS atlas, thus allowing an estimation of the volumes of fibroglandular tissue. Varying its proportions will allow the quantitative assessments of breast density to be performed.

3.6 Conclusion

In this study, a patient-specific 3D-printed breast phantom was successfully constructed using silicone and peanut oils to simulate the MR-related characteristics of breast fibroglandular and adipose tissues. The proposed methodologies can be used as a preliminary work for breast structure simulations and the construction of further patient models using MRI dataset. The phantom can be used to test different breast MR imaging protocols to determine the optimum scanning parameters and analysis algorithms for the quantitative assessment of breast density.

4. Chapter 4

Quantitative Measurement of Breast Density Using

Personalized 3D-Printed Breast Model for Magnetic

Resonance Imaging

4.1 Abstract

Despite the development and implementation of several MRI techniques for breast density assessments, there is no consensus on the optimal protocol in this regard. This study aimed to determine the most appropriate MRI protocols for the quantitative assessment of breast density using a personalized 3D-printed breast model. The breast model was developed using silicone and peanut oils to simulate the MRI related-characteristics of fibroglandular and adipose breast tissues, and then scanned on a 3T MRI system using non-fat-suppressed and fat-suppressed sequences. Breast volume, fibroglandular tissue volume, and percentage of breast density from these imaging sequences were objectively assessed using Analyze 14.0 software. Finally, the repeated-measures analysis of variance (ANOVA) was performed to examine the differences between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density with respect to the corresponding sequences. The volume of fibroglandular tissue and the percentage of breast density were significantly higher in the fat-suppressed sequences than in the non-fat-suppressed sequences ($p < 0.05$); however, the difference in breast volume was not statistically significant ($p = 0.529$). Further, a fat-suppressed T2-weighted with turbo inversion recovery magnitude (TIRM) imaging sequence was superior to the non-fat- and fat-suppressed T1- and T2-weighted sequences for the quantitative measurement of breast density due to its ability to represent the exact breast tissue compositions. This study shows that the fat-suppressed sequences tended to be more useful than the non-fat-suppressed sequences for the quantitative measurements of the volume of fibroglandular tissue and the percentage of breast density.

4.2 Introduction

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, has been determined as an independent risk factor for developing breast cancer.¹⁻⁴ Previous studies have reported that the potential risk of breast cancer in women with dense breasts is three- to five-fold higher than in women with fatty breasts.⁵⁻⁷ Recent developments in breast cancer screening have intensified the need for a standardized imaging protocol and/or measurement method for the evaluation of breast density predominantly for women at an elevated risk of developing breast cancer, such as those with high breast density.^{4,8-10} A considerable amount of literature has been published on the assessment of breast density with several methods and algorithms proposed to segment and/or measure breast density using MRI datasets.¹¹⁻¹⁹ Nevertheless, research has consistently shown that these methods/algorithms seem to have certain drawbacks, mostly due to the use of a semi-automatic approach or a high-level of dependency on user interaction. Likewise, numerous MR breast-imaging protocols have been applied to the screening and/or the assessment of breast density, ranging from contrast- to non-contrast-enhanced imaging with or without the implementation of fat-suppression techniques.^{3,4,8-10,20-25} To date, there has been little consensus on the optimal MR breast-imaging protocol and measurement method for breast density screening and/or assessment, especially in the context of women with dense breast tissues.

The dynamic contrast-enhanced (DCE)-MRI technique has been widely used for the screening of women at high risk of breast cancer and has been included in standard clinical breast MRI protocols.^{4,8} Despite its long clinical success, DCE-MRI has certain disadvantages, such as long scanning time, high cost, and potential harm caused

by the contrast agent.^{4,26} Although contradictory findings have been reported in the literature about the precipitation and accumulation of gadolinium contrast-based agents in the brain, there is no general agreement regarding the risk of repeated gadolinium administration.^{4,27–29} Nevertheless, questions have been raised about the safety of prolonged use of DCE-MRI as a primary screening method for the detection of breast cancer and/or the assessment of breast density. On the other hand, the fat-suppression technique has been suggested in breast MRI to improve the visibility of pathology, contrast enhancement, and image quality, thus allowing for better differentiation between dense fibroglandular and non-dense fatty tissues.^{17,30} It has been combined with other techniques and/or sequence types due to the difficulty of eliminating the high signal intensity associated with fatty tissues.^{17,30} Several methods have been proposed for fat suppression in breast MRI, including chemical shift spectral-selective saturation (CHESS) based on the chemical shift variation between fat and water, inversion recovery (IR) based on variation in T1 relaxation time, hybrid CHESS–inversion recovery methods, and Dixon fat–water separation based on phase variation between fat and water signals at different echo times (TEs).^{3,17,20,30–32}

Non-fat-suppressed and fat-suppressed T1-weighted images are frequently used with either 2D spin echo (SE) or 3D gradient echo (GRE) in standard clinical breast MRI protocols.^{8,17} Nevertheless, there is no consensus as to which of these sequences/techniques is the most efficient in this regard. The American College of Radiology (ACR) has recommended that the fat-suppressed images with high spatial resolution be used in clinical breast MRI protocols as images acquired with this sequence can eliminate misregistration, which mainly occurs when a patient moves during the acquisition of pre- and post-contrast images.^{8,17} However, this recommendation contrasts with that of the European Society of Breast Imaging

(EUSOBI), which considers non-fat-suppressed sequences based on the acquisition of subtraction images more useful.^{17,33} Despite this, there seems to be some consensus that other breast MRI techniques, including T2-weighted images, DCE, and diffusion-weighted imaging (DWI), tend to benefit from its combination with fat-suppression techniques for several reasons.^{1,8,17,30} For instance, turbo inversion recovery magnitude (TIRM), a type of inversion recovery sequence with the advantage of short image acquisition time, has been widely used in the delineation of tumor and/or lymphatic spread and could possibly be combined with fat-suppression technique for the assessment of breast density.^{4,34} Patient-specific 3D-printed breast models, derived from a patient's MR imaging data and comparable to the anatomical structures of human tissues, can be a valuable tool for examining different breast MRI protocols, testing the radio frequency coils, and evaluating system performance.³⁵⁻⁴² The aim of this study is to determine the most appropriate MR breast-imaging protocols for the quantitative assessment of breast density using a personalized 3D-printed breast model based on an objective comparison between the non-fat-suppressed and fat-suppressed sequences. We hypothesize that fat-suppressed sequences allow for more accurate assessment of breast density while TIRM with fat-suppressed sequence further enhances its accuracy in quantitative assessment of breast density.

4.3 Materials and Methods

4.3.1 Study Subject: A Personalized 3D-Printed Breast Model

A personalized 3D-printed breast model which was developed in our previous study⁴³ used 3D-printing techniques and tissue-mimicking materials (TMMs) with the intention of simulating the MR-related characteristics of fibroglandular and adipose breast tissues for the quantitative assessment of breast density. The model consisted of

two main parts: an outer shell to simulate the breast outline, and an inner shell filled with silicone and peanut oils to mimic the internal breast compositions. The results showed that the silicone and peanut oils successfully resemble the MR-imaging characteristics and T1 relaxation times of fibroglandular and adipose breast tissues, respectively.⁴³ This combination of findings further supports the hypothesis that such a model could be used to examine different MR breast-imaging protocols in order to determine the optimum for the quantitative assessment of breast density. Figure 4.1 demonstrates the schematic flowchart of the construction process for developing a personalized 3D-printed breast model.

4.3.2 MR Scanning Protocol

The 3D-printed breast model was scanned on a 3T MRI system (MAGNETOM Prisma, Siemens Healthcare, Erlangen, Germany) in a prone position using a dedicated 18-channel breast coil. Different MR imaging sequences were applied to improve the visibility of structure and contrast enhancement, thus allowing for better differentiation between fatty non-glandular and glandular structures. The site's standard clinical breast MRI protocols of the site were used with no further modification and/or adjustment to the technical parameters. Table 4.1 displays the image acquisition parameters of the six MR imaging sequences used in this study.

Figure 4.1. Flow chart demonstrates the construction process of the personalized 3D-printed breast model for MRI.⁴³

4.3.3 Quantitative Measurement: Breast Volume, Fibroglandular Tissue Volume, and Percentage of Breast Density

Breast volume and fibroglandular tissue volume were objectively measured with a semi-automated segmentation method using a commercially available biomedical imaging software, Analyze V 14.0 (AnalyzeDirect, Inc., Lexana, KS, USA). Two steps

were performed to measure the percentage of breast density from MRI data: breast segmentation and fibroglandular tissue segmentation. The purpose of breast segmentation is to separate the breast's body from the surrounding structure and/or background, while fibroglandular tissue segmentation separates the glandular from the fatty tissue.

To differentiate the breast's body from the background, the breast's boundary was first delineated semi-automatically using an interactive tool based on the threshold signal intensity function by setting seed points on a series of 2D axial slices comprising the entire breast volume. The minimum and maximum threshold limits were then adjusted to define the region of interest. The software spontaneously interpolated between these slices and generated a mask of the whole breast volume. Once the breast's body was segmented out, an automated method incorporating several morphological processing operations and spatial filters were used to segment out the fibroglandular tissue from the surrounding fatty tissue. Upon completion of this segmentation process, the breast volume and fibroglandular tissue volume were measured using a 3D-measurement tool based on the size intensity function. The percentage of breast density was then computed as the ratio of the fibroglandular tissue volume relative to the total breast volume. Finally, the results were analyzed to assess the differences between the measurement of breast volume, fibroglandular tissue volume, and percentage of breast density based on the different MRI sequences.

4.3.4 Data Synthesis

The acquisition of the different MRI sequences and the implementation of several fat-suppression techniques, as applied in the proposed study, are considered to be

technically heterogeneous. To address this complexity and provide more objective comparisons, the six MRI sequence compartments were re-configured into a two-way cross-classification, namely two fat-suppression categories: non-fat-suppression MRI sequences (i.e., MR Seq. 1, 2, and 3) and fat-suppression MRI sequences (i.e., MR Seq. 4, 5, and 6). For the purpose of the analysis, the segmentation processes of both the breast volume and the fibroglandular tissue volume were performed three times, thus extracting three segments from each MRI sequence. Subsequently, the measurements were conducted three times with respect to the volume of the breast, the volume of the fibroglandular tissue, and, thereby, the percentage of the breast density.

4.3.5 Statistical Analysis

Statistical analyses were conducted using NCSS V 19.0.5 (NCSS, LLC., Kaysville, UT, USA). The repeated-measures analysis of variance (ANOVA) was performed to examine the difference between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density with regard to the non-fat-suppressed and fat-suppressed MRI sequences. This variance model was employed to account for the variation both between sequences (i.e., between subjects) and within repeated measurements (i.e., within subjects). Significance levels were set at the 5% level. Descriptive data and box plots were also produced for all variables, demonstrating the distribution and median of breast volume, fibroglandular tissue volume, and percentage of breast density measured in the non-fat-suppressed and fat-suppressed imaging groups.

Table 4.1. Image acquisition parameters of the MR breast-imaging sequences using a personalized 3D-printed breast model.

No.	MRI sequence	Acquisition type	Orientation, Slice No.	TR (ms)	TE (ms)	TI (ms)	FOV (mm)	Matrix size	Slice thickness (mm)	Flip angle (°)	NSA	Scan time (min)
1.	Non-fat-suppressed TSE (T2W)	2D	Axial, 33	6080	78	-	350×350	336×448	4.0	80	1	1.10
2.	Non-fat-suppressed TSE (T1W)	2D	Axial, 37	709	10	-	350×350	224×320	2.9	130	2	2.38
3.	Non-fat-suppressed TSE SPACE (T1W)	3D	Axial, 88	600	3.4	-	400×400	256×256	1.6	120	2	2.47
4.	Fat-suppressed TSE SPACE (T1W)	3D	Axial, 88	1500	3.4	-	400×400	256×256	1.6	120	1	4.58
5.	Fat-suppressed TSE SPACE SPAIR (T1W)	3D	Axial, 88	1500	3.4	-	400×400	256×256	1.6	120	1	4.58

4.4 Results

4.4.1 Scanning of the Personalized 3D-Printed Breast Model

Figure 4.2 shows the MR images of the personalized 3D-printed breast model using silicone and peanut oils as surrogates for fibroglandular and fatty breast tissues, respectively, for the various scanning sequences. These oils produced a reasonable level of contrast and MR-related characteristics amongst the T1- and T2-weighted images with and without the implementation of the fat-suppression techniques. Although the most noticeable feature of the personalized 3D-printed breast model was that it was somewhat inhomogeneous, this feature nevertheless mimics the substantial inhomogeneity sometimes encountered in patients' irregular distributions. The used tissue-mimicking materials for simulating the MR imaging characteristics for fibroglandular and adipose tissues have been induced similar appearance, variability, and heterogeneity of the breast structures that seen in the physiological tissues.

The suppression of fat signals in the T1-weighted images with both SPACE and SPAIR acquisitions did not substantially increase the contrast enhancement or visualization between the dense fibroglandular and non-dense fatty structures (Figure 4.2D, E). A possible explanation for this could be that these types of acquisitions are highly affected by inhomogeneity in the magnetic field, demonstrating inhomogeneous fat suppression in the fatty structures. On the contrary, Figure 4.2F shows that the fat-suppressed T2-weighted image with TIRM acquisition demonstrated a homogenous high signal intensity in the fibroglandular structure and a low signal intensity in the fatty structure for both the right and left breasts. The suppression of fat signals significantly improved the contrast between the

fibroglandular and fatty structures, further enhanced visualization, and provided more anatomical information which may assist in the segmentation and/or quantification of breast density.

Figure 4.2. Central axial slice of a personalized 3D-printed breast model for the different MR imaging pulse sequences. **(A)** Non-fat-suppressed TSE (T2W); **(B)** Non-fat-suppressed TSE (T1W); **(C)** Non-fat-suppressed TSE SPACE (T1W); **(D)** Fat-suppressed TSE SPACE (T1W); **(E)** Fat-suppressed TSE SPACE SPAIR (T1W); **(F)** Fat-suppressed IR/PFP TIRM (T2W). For pulse sequences, refer to Table 4.1.

4.4.2 Quantitative Measurement of Breast Volume, Fibroglandular Tissue Volume, and Percentage of Breast Density

Table 4.2 displays the quantitative measurements (mean and standard deviations) of the breast volume, fibroglandular tissue volume, and percentage of breast density for the different MRI sequences. For the SPACE T1-weighted images (i.e., MR Seq. 3 and 4), there was evidence of a difference in breast density between the non-fat-suppressed sequence ($7.719 \pm 0.366\%$) and the fat-suppressed sequence ($11.698 \pm 0.351\%$). This difference can be explained by the direct relationship between fibroglandular tissue volume and breast density, as shown in Table 4.2, the volume of fibroglandular tissue measured in the fat-suppressed sequence (i.e., MR Seq. 4) was higher than that in the non-fat-suppressed sequence (i.e., MR Seq. 3): $53.940 \pm 1.083 \text{ cm}^3$ and $34.261 \pm 1.809 \text{ cm}^3$, respectively.

For the breast density assessment, there was a substantial difference between the non-fat-suppressed sequence ($5.401 \pm 0.165\%$) and the fat-suppressed sequence ($9.498 \pm 0.930\%$) measured in the T2-weighted images, MR Seq. 1 and MR Seq. 6, respectively. This difference might explain the relatively good improvement in the contrast between the fibroglandular and fatty structures (Figure 4.2F) owing to the implementation of the fat-suppression technique, which had a major effect on the segmentation process and, therefore, the measurement of breast density. By contrast, the means of the breast density for the non-fat suppressed (i.e., MR Seq. 2) and the fat-suppressed (i.e., MR Seq. 5) were $7.733 \pm 0.365\%$ and $10.467 \pm 0.084\%$, respectively. A comparison of MR Seq. 2 and MR Seq. 5 revealed that the breast volume, fibroglandular tissue volume, and percentage of breast density measured in the fat-

suppressed sequence tended to be higher than that measured in the non-fat-suppressed sequence (Table 4.2).

Table 4.2. Results of the estimated mean and standard deviation of breast volume, fibroglandular tissue volume, and percentage of breast density for the different MRI sequences using a personalized 3D-printed breast model.

MRI sequence*	Breast volume (cm ³)		Fibroglandular tissue volume (cm ³)		Breast density (%)	
	Mean	SD	Mean	SD	Mean	SD
Non-fat-suppression group (MR Sequences 1, 2, and 3)						
MR Seq. 1 (N = 3)	592.291	5.065	31.984	0.735	5.401	0.165
MR Seq. 2 (N = 3)	388.793	4.159	30.067	1.159	7.733	0.365
MR Seq. 3 (N = 3)	443.884	11.913	34.261	1.809	7.719	0.366
Combined (N = 9)	474.989	91.406	32.104	2.144	6.952	1.194
Fat-suppression group (MR Sequences 4, 5, and 6)						
MR Seq. 4 (N = 3)	461.188	4.699	53.940	1.083	11.698	0.351
MR Seq. 5 (N = 3)	462.948	11.882	48.456	1.140	10.467	0.084
MR Seq. 6 (N = 3)	715.784	32.097	67.794	3.623	9.498	0.930
Combined (N = 9)	546.640	128.031	56.730	8.854	10.555	1.077

*For pulse sequences, refer to Table 4.1.

4.4.3 Comparison of Measurements Between Non-Fat-Suppression and Fat-Suppression Groups

Table 4.3 demonstrates the results (mean, standard error, F-ratio, and P-value) of the repeated-measures ANOVA of breast volume, fibroglandular tissue volume, and percentage of breast density with respect to the non-fat-suppression and fat-suppression groups. The box plots of these parameters for the two groups are shown in Figure 4.3.

Table 4.3. Results of the repeated-measures ANOVA, including total mean, standard error (SE), F-ratio, probability level (Prob level) of breast volume, fibroglandular tissue volume, and percentage of breast density between two imaging groups: non-fat-suppressed and fat-suppressed MRI pulse sequences.

Breast Density Parameter	Non-fat-suppressed (N = 9)		Fat-suppressed (N = 9)		F-ratio	Prob level**
	Mean	SE (4 df*)	Mean	SE (4 df*)		
Breast volume (cm ³)	474.989	73.639	546.640	73.639	0.47	0.5293
Fibroglandular tissue volume (cm ³)	32.104	4.158	56.730	4.158	17.54	0.0138
Breast density (%)	6.952	0.709	10.555	0.709	12.90	0.0229

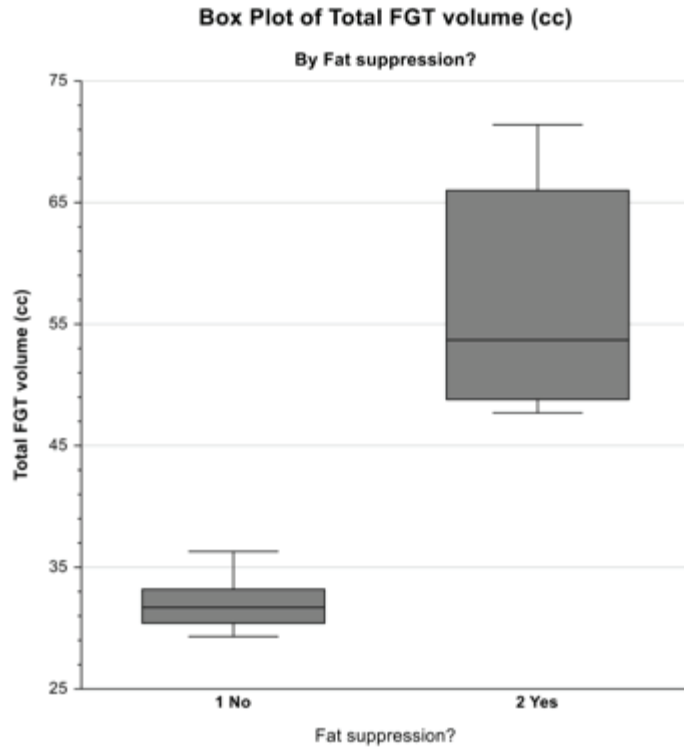

*The degrees of freedom; **The significance level of the F-ratio (the probability that the difference between data is significant or not). The significant difference between the quantitative measurements of breast volume, fibroglandular volume, and percentage of breast density based on the non-fat suppressed and the fat-suppressed MRI sequences was determined at the 5% level.

For breast volume, although the mean measured from the non-fat-suppression group (474.989 cm³) tended to be lower than that from the fat-suppression group (546.640 cm³), the difference was not statistically significant (p = 0.5293), with an F-ratio of 0.47 and a standard error for both means of 73.639. However, for the fibroglandular

tissue volume and the percentage of breast density, the repeated-measures ANOVA showed that the difference between the non-fat-suppression group and the fat-suppression group was statistically significant at the 5% level. The values measured from the non-fat-suppression group were lower than those from the fat-suppression group, as shown in Table 4.2; Table 4.3. The mean volume of fibroglandular tissue was 32.104 cm³ for the non-fat-suppression group and 56.730 cm³ for the fat-suppression group, which was statistically significant ($F = 17.54$; $p = 0.0138$), with a standard error of 4.158. Likewise, there was a significant difference ($F = 12.90$; $p = 0.0229$) between the two groups: the mean breast density measured in the non-fat-suppression group (6.952%) tended to be lower than that of the fat-suppression group (10.555%), with a standard error for both means of 0.709.

(A)

(B)

(C)

Figure 4.3. Box plots demonstrate the distribution and median of three main parameters: (A) breast volume, (B) fibroglandular tissue volume, and (C) percentage of breast density measured on the non-fat-suppressed and the fat-suppressed MRI sequences. The six MRI sequences compartments were re-configured into a two-way cross-classification, namely two fat-suppression categories. As shown,

“1/No” is the non-fat-suppression, “2/Yes” is the fat-suppression, which are on the x-axis, while the three parameters measured with respect to these two corresponding categories are on the y-axis.

4.5 Discussion

Recently, for women with an elevated risk of developing breast cancer, such as those with high breast density, the importance of establishing a standardized MRI protocol and/or measurement method for the assessment of breast density has increased in clinical and research domains. Although fat-suppressed and non-fat-suppressed sequences have frequently been included for both T1- and T2-weighted images in clinical breast MRI protocol, there is no agreement on which of these sequences should be used in this regard.^{1,8,17,30} The current study was designed to determine the most appropriate MRI sequence for the quantitative assessment of breast density using a personalized 3D-printed breast model⁴³ based on an objective comparison between fat-suppressed and non-fat-suppressed sequences. Six MRI sequences were acquired and categorized into fat-suppression and non-fat-suppression categories to examine the difference between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density between these two imaging groups.

Comparing the two fat-suppression groups, the repeated-measures ANOVA showed that the differences between the non-fat-suppressed and fat-suppressed MRI sequences (i.e., MR Seq. 1, 2, and 3 and MR Seq. 4, 5, and 6) were statistically significant at the 5% level for both fibroglandular tissue volume and percentage of breast density. On the contrary, the observed difference between these corresponding sequences was not statistically significant with respect to breast volume. The current findings seem to be consistent with other research documenting that the assessment of breast density is considered to fluctuate with MRI sequences and with the application of fat-suppression

techniques.^{3,16,17} A comparison of our results with Chang et al,¹⁷ who suggested that breast volumes measured in T1-weighted sequences with and without fat suppression were almost identical for a similar case, is encouraging. Although their results differed from the current study, given that the breast density parameters were analyzed only on the T1-weighted sequences, they are still consistent with our findings, which showed that there was no evidence of a difference in the breast volumes between the non-fat-suppression and the fat-suppression groups (Table 4.3). A possible explanation for this could be that the measurement of breast volumes based on these two groups was not considerably influenced by the applied imaging techniques and/or segmentation method. Despite the breast volumes measured from the T2-weighted sequences with and without fat suppression being higher than those of the T1-weighted sequences, the difference between the two imaging groups was not significant. This can be attributed to the matrix sizes of the T2-weighted images used with the non-fat-suppressed and fat-suppressed sequences (i.e., MR Seq. 1 and 6), which were 336×448 and 358×448 , respectively.

However, there was a statistically significant difference between fibroglandular tissue volume and percentage of breast density, indicating higher values in the fat-suppressed sequences (MR Seq. 4, 5, and 6) compared to the non-fat-suppressed sequences (MR Seq. 1, 2, and 3), as shown in Tables 4.2 and 4.3. This difference can be explained in part by the relatively good contrast enhancement and/or visualization observed between the fibroglandular and the fatty structures resulting from the suppression of fat signals, as was evident in the TIRM with fat-suppressed T2-weighted image (Figure 4.2F). Although the signal-to-noise ratio and tissue contrast in the non-fat-suppressed images were higher than those in the fat-suppressed images, the results for the fat-suppression group were significantly higher than those for the non-fat-suppression

group. Nevertheless, the scanning times for the fat-suppressed sequences were longer than those for the non-fat-suppressed sequences, except for the TIRM, which was 1 min 51 s. As shown in Table 4.2, breast volume, fibroglandular tissue volume, and percentage of breast density analyzed with TIRM were considerably higher than those of the T1- and T2-weighted sequences with and without fat suppression. Compared to these sequences, the observed increase in breast density parameters from the T2-weighted and TIRM acquisition was probably due to their individual characteristics: the T2-weighted image with fat-suppression technique is known to improve fluid intensity visualization, while TIRM is known to provide more anatomical information.^{4,44} Similar findings were obtained by Bu et al,⁴ who suggested that the combined DWI and TIRM could be used as an alternative imaging protocol for the screening of women with dense breast tissue. Despite being preliminary findings, our study indicates that TIRM could be incorporated with fat-suppression techniques for the assessment of breast density. Therefore, the fat-suppressed T2-weighted image with TIRM acquisition can be a promising technique for the quantitative assessment of breast density, although further research should be conducted to verify this suggestion.

Overall, the observed differences in breast density measurements between the fat-suppression and non-fat-suppression groups can be attributed to several factors: the segmentation method, image quality, scanning/technical parameters, and tissue contrast achieved by using different MRI pulse sequences. There are, however, other possible reasons; the applied fat-suppression techniques are more susceptible to magnetic field inhomogeneity, especially in the case of the 3T MRI system, where the field heterogeneity can be more protuberant. As shown in Figure 4.2, the high levels of inhomogeneity in both the fat-suppressed and non-fat-suppressed images might be

the major factor—if not the only factor—that can cause such a variation in the segmentation and/or quantification of breast density parameters.

Although this study suggests that the fat-suppressed sequences are more useful than the non-fat-suppressed sequences for the segmentation/measurement of fibroglandular tissue volume and breast density, it is subject to several limitations. First, the assessment of breast density parameters was carried out on a developed 3D-printed breast model using silicone and peanut oils as tissue-equivalent materials and may not reflect the exact distribution of both fibroglandular and fatty structures as seen in human breast tissues. This limitation could be addressed by further research with the use of more realistic breast models for MRI scanning. Second, the high levels of inhomogeneity in both the fat-suppressed and non-fat-suppressed images could have influenced the segmentation and breast density measurements. This is unavoidable due to the complexity of the MRI scanning sequences. Third, the breast density parameters were segmented and measured using a semi-automated method, which implies that the prospective source of variation between such measurements could be due to a high level of dependency on user interaction. For this reason, multiple segmentations/measurements of the breast density parameters were consistently conducted by the same observer to minimize potential intra-observer variations. However, the applicability of the proposed segmentation and measurement method is relatively high as an interactive 3D tool and would be more useful in the long-term assessment of breast density. Finally, with the implementation of different imaging techniques, acquisition types, and fat-suppression methods, caution must be applied as the findings might not be transferable to clinical practice without further investigation.

For future research, a greater focus on the TIRM with a fat-suppression technique could produce interesting findings on the quantification of breast density, especially for women at high risk of developing breast cancer. Quantitative assessment of breast density parameters in participants' clinical breast MRI datasets, could also be used to investigate and validate this observation.

4.6 Conclusion

A significant difference was found between the non-fat-suppression and fat-suppression MRI sequences for the quantitative measurements of the volume of fibroglandular tissue and the percentage of breast density. In general, the findings suggest that fat-suppressed sequences are an efficient scanning technique that reflects the exact composition of breast tissues. TIRM with fat-suppressed T2-weighted sequence can be a promising imaging protocol for the segmentation and/or quantification of breast density. Further research is required to verify these findings so that the optimal breast MRI protocols can be developed for clinical application.

Quantitative Measurement of Breast Density in a High-risk Group Using Fat-suppressed and Non-fat-suppressed T2-weighted Magnetic Resonance Imaging Sequences

5.1 Abstract

Background: T2-weighted imaging is one of the standard magnetic resonance imaging (MRI) protocols used in breast scanning. However, the relative role of T2-weighted images with/without the use of fat-suppression techniques in the quantitative assessment of breast density remains limited across a variety of T2-weighted sequences. **Purpose:** This study aimed to investigate the difference between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density of two MR techniques, the non-fat-suppressed versus the fat-suppressed T2-weighted imaging sequences in a cohort of 11 high-risk women. **Methods:** Breast volume, fibroglandular tissue volume, and percentage of breast density from these imaging techniques were quantitatively measured using the Analyze 14.0 software. Averages of repeated-measures observations were conducted using the Bland-Altman comparison of measurements to examine the difference between the non-fat-suppressed and fat-suppressed T2-weighted sequences with regard to the quantitative assessments of breast density parameters. **Results:** The results revealed no indication of measurement bias between the non-fat-suppressed and fat-suppressed T2-weighted imaging sequences with respect to breast density parameters, and no evidence to reject the presumption that the differences were normally distributed. Although the volume of fibroglandular tissue and the percentage of breast density were higher in the non-fat-suppressed sequence than in the fat-suppressed sequence, the differences were not statistically significant ($p > 0.05$). **Conclusions:** This study showed no substantial differences between the non-fat-suppressed and fat-suppressed sequences in the quantitative measurement of breast density parameters; however, further studies with inclusion of a larger sample size are required to validate the complementary role of T2-weighted imaging in this regard.

5.2 Introduction

Breast density, a measure of dense fibroglandular tissue compared to fatty, non-dense tissue, is an independent risk factor for breast cancer.¹⁻⁴ Evidence suggests that the prospective risk of breast cancer is three to five times higher for women with dense breasts than for women with fatty breasts.⁵⁻⁷ Most information about breast density estimation and screening for breast cancer is obtained through full-field digital mammography (FFDM), a two-dimensional imaging technique.^{8, 9} However, the evaluation of breast density based on mammograms is limited due to tissue overlapping, variations in breast compression, and inappropriate positioning, which can lead to artefacts and insufficient imaging of breast tissue.^{10, 11} Magnetic resonance imaging (MRI), an adjuvant modality of breast imaging, has been proposed to be used in women at high risk of developing breast cancer, such as those with the breast cancer susceptibility gene (BRCA-positive genetic mutation carriers), a family history of breast cancer, and high breast density.¹²⁻¹⁵ MRI has been used to estimate actual breast density because it provides a three-dimensional volume representation of breast structure with excellent soft tissue contrast, which assists in the differentiation between fibroglandular and fatty, or adipose tissues.¹⁶⁻¹⁹

Conventionally, the evaluation of breast density is based on a qualitative approach recommended by the American College of Radiology (ACR) Breast Imaging

Reporting and Data System (BI-RADS), which classifies density into four categories based on the amount of fibroglandular tissue: 1) almost entirely fat; 2) scattered fibroglandular tissue; 3) heterogeneous fibroglandular tissue; and 4) extreme fibroglandular tissue.^{20, 21} Despite standardization guidelines, however, research has consistently shown that BI-RADS scores are subjective and vary between readers, resulting in inter- and even intra-reader variability.²²⁻²⁴ Various methods of quantifying breast density, with a variety of algorithms or techniques documented in the literature, have been proposed to address this limitation.²⁵⁻³¹ Nevertheless, in the quantitative assessment of breast density, these methods were based on a semi-automatic thresholding and/or segmentation methodology, and much uncertainty remains about the optimal method in this regard.²⁵⁻³² Similarly, for the evaluation of breast density, different MR breast-imaging protocols and/or sequences have been used, varying from contrast- to non-contrast-enhanced imaging with/without the application of fat-suppression techniques.^{3, 4, 32-40}

The inversion-based technique known as the short-TI inversion recovery (STIR) sequence is among the most widely used fat-suppression techniques in breast imaging due to its insensitivity to B_0 and B_1 heterogeneity.^{41, 42} STIR is obtained by a 180° non-spectral-selective inversion pulse followed by either a single 90° pulse or a pair of 90° and 180° pulses for inversion recovery (IR) and spin-echo (SE) imaging, respectively.^{36, 38, 41-43} Although fat-suppression techniques have been shown to enhance the visibility of pathology, contrast enhancement, and image quality, thereby allowing for a better differentiation between fibroglandular and fatty tissue, no agreement has yet been reached on which MR breast-imaging protocols are appropriate for the quantitative assessment of breast density, particularly for women at high risk of developing breast cancer.^{41, 44} Fundamentally, the MRI studies used

T2-weighted images to identify diseased tissue in almost all parts of the body; while T2-weighted turbo spin-echo (TSE) pulse sequences have been widely reported in breast MRI to help classify lesion characterization and thus improve the differential diagnosis, their complementary role in breast density assessment remains largely unexplored.⁴⁵⁻⁴⁸

The primary aim of this study was to investigate the differences between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density of two MR techniques, non-fat-suppressed T2-weighted TSE versus fat-suppressed T2-weighted STIR imaging sequences, in a cohort of high-risk women. The tested hypothesis was that the T2-weighted image features with/without the use of fat-suppression techniques can assist in the differentiation of fibroglandular and fatty tissue, allowing for more accurate measurement of breast density parameters, thus highlighting the potential risk of developing breast cancer in high-risk women.

5.3 Materials and Methods

5.3.1 Study Subjects and MR Scanning Protocol

The study group consisted of 11 female subjects who had breast MRI examinations conducted between 2009 and 2010. All participants were cancer-free but at high risk of developing breast cancer and confirmed to be normal without prior breast surgery or radiation therapy on the chest wall. MRI studies were performed on a 1.5T system (Philips, Best, The Netherlands) in a prone position using a dedicated bilateral 8-channel breast coil. The imaging protocol included axial non-fat-suppressed T2-weighted TSE and fat-suppressed T2-weighted STIR images. The version of two-

dimensional-STIR imaging used in this study employed a 180° non-spectral-selective inversion pulse followed by a single 90° pulse for the fat-suppression technique. In all cases, both the imaging acquisitions used for the quantitative assessment of breast density parameters were acquired before the injection of contrast for the T1-weighted dynamic contrast-enhanced imaging. Table 5.1 shows the image acquisition parameters of the MRI sequences used in this study.

5.3.2 Quantitative Measurement: Breast Volume, Fibroglandular Tissue Volume, and Percentage of Breast Density

With a semi-automated segmentation/measurement method, breast volume and fibroglandular tissue volume were quantitatively assessed using commercially available biomedical imaging software, Analyze V 14.0 (AnalyzeDirect, Inc., Lexana, KS, USA). Two steps were implemented to measure the percentage of breast density from MRI volumes: breast segmentation and fibroglandular tissue segmentation. Breast segmentation is proposed to separate the breast's body from the surrounding structure, while segmentation of fibroglandular tissue separates the glandular tissue from the fatty tissue.

The breast's boundary was first semi-automatically delineated to separate the breast's body from the surrounding structures, using an interactive method based on the threshold signal intensity function by placing seed points on a series of 2D axial slices comprising the whole volume of the breast. To identify the region of interest, the minimum and maximum threshold limits were then modified. The software impulsively interpolated between these slices and produced a mask of the entire breast volume. Once the breast segmentation process was completed, an automated method, using a variety of morphological processes and spatial filters, was carried out to

segment the fibroglandular tissue from the surrounding fatty tissue. Following this, the volume of the breast and the volume of fibroglandular tissue were quantified using a 3D-measuring tool based on the size intensity function. Finally, the ratio of the fibroglandular tissue volume relative to the total breast volume was determined as the percentage of breast density.

5.3.3 Data Synthesis

In this retrospective study, the MRI data for 11 high-risk women were examined. The women were recruited from The Cancer Imaging Archive (TCIA) Public Access (<https://www.cancerimagingarchive.net>), and both non-fat-suppressed T2-weighted TSE and fat-suppressed T2-weighted STIR images were available for them. For each woman, a two-fold segmentation of both the breast volume and the fibroglandular tissue volume was performed, thus extracting two segments of each MRI sequence. Consequently, the measurements were conducted twice with respect to the breast volume, the fibroglandular tissue volume, and thus the percentage of breast density. Finally, the average of each pair of values was calculated as a final observation for each patient/MRI sequence combination and reflected as an estimate of the true numerical value of each of the subjects of interest in the analysis (i.e. breast density parameters). This aimed to avoid the variance from causing significant underestimation/overestimation of other variance components.

5.3.4 Statistical Analysis

Statistical analyses were conducted using NCSS V 19.0.5 (NCSS, LLC. Kaysville, Utah, USA). Averages of repeated-measures observations through the Bland-Altman comparison of measurements were conducted to examine the difference between the

non-fat-suppressed T2-weighted TSE and the fat-suppressed T2-weighted STIR MRI sequences with regard to the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density. The null hypothesis was that the differences between the two MRI sequences would all be zero throughout the range.

The Bland-Altman model was employed to test the outcomes on the assumption that both measurement methods (i.e. two MRI sequences) would yield exactly the same numerical value of the metric of interest (i.e. breast volume, fibroglandular tissue volume, and percentage of breast density) and provide a graphical representation of bias, if any, in one method relative to the other. The Bland-Altman scatter plots were produced for the two MRI sequences, demonstrating the difference against the average, which illustrates a system with zero bias of one method relative to the other with respect to breast volume, fibroglandular tissue volume, and percentage of breast density. The normality assumptions of the datasets distributed were also examined using the Shapiro-Wilk, Skewness, Kurtosis, and Omnibus tests. Statistical significance was evaluated using the one-sample t-test as appropriate and set at the 5% level.

Table 5.1. Image acquisition parameters of the MR breast-imaging sequences used in this study.

Patient No.	MRI sequence	Acquisition type	Orientation, Slice No.	TR (ms)	TE (ms)	TI (ms)	FOV (mm)	Matrix size	Slice thickness (mm)	Flip angle (°)	NSA	Scan time (min)

Abbreviations: TR: repetition time; TE: echo time; TI: inversion time; FOV: field-of-view; NSA: number of signal averages/excitations; T2W: T2-weighted; TSE: turbo spin-echo; STIR: short-TI inversion recovery; 2D: two-dimensional.

5.4 Results

5.4.1 Quantitative Measurement of Breast Volume, Fibroglandular Tissue Volume, and Percentage of Breast Density

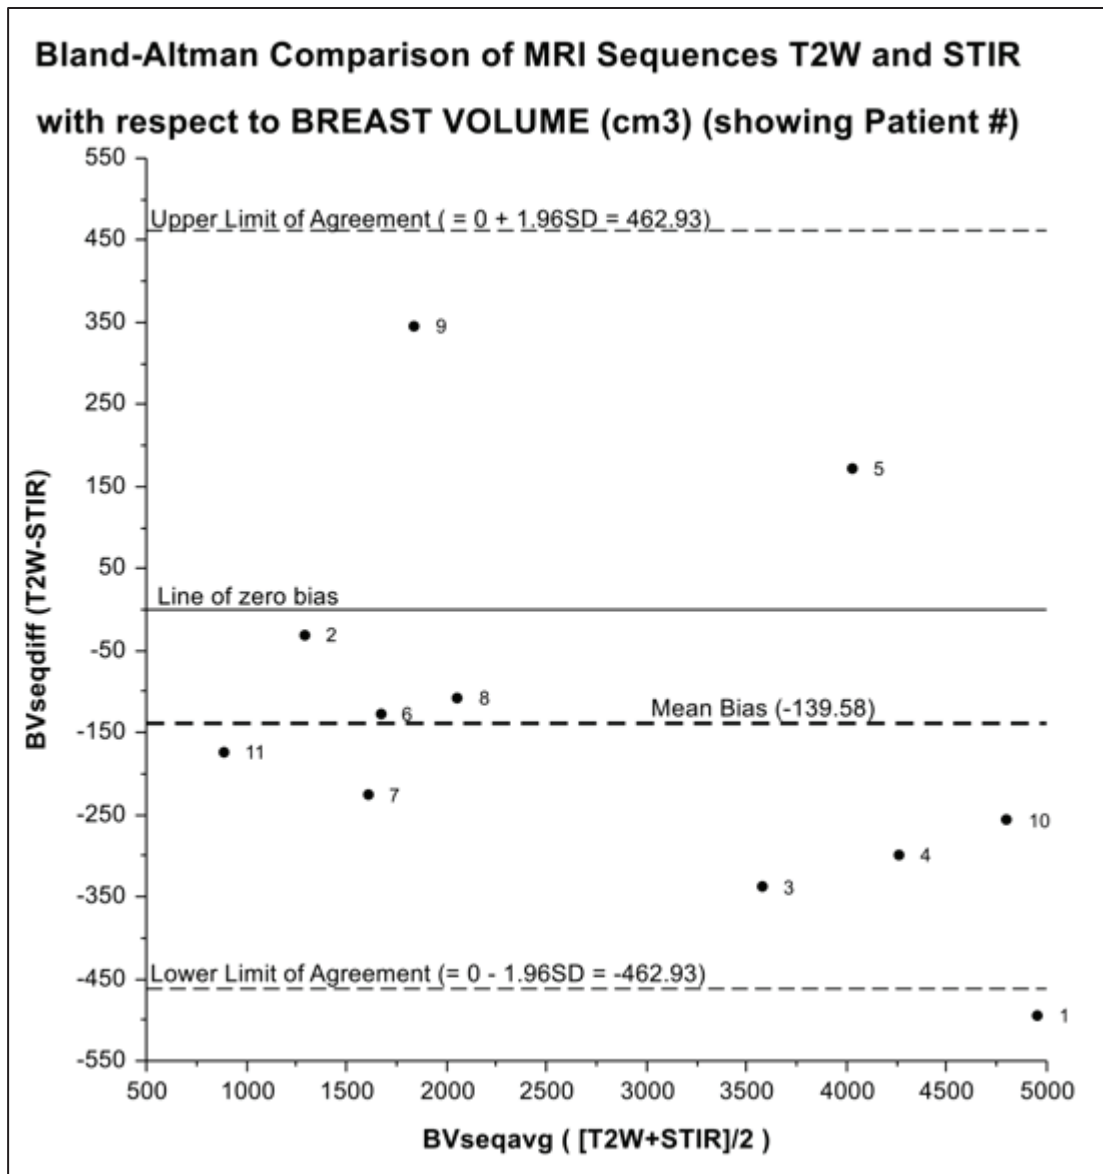

Table 5.2 provides the quantitative measurements (average and SD) of the breast volume, fibroglandular tissue volume, and percentage of breast density measured on these two MRI sequences. The differences between the two MRI sequences and their averages are highlighted in Table 5.3.

5.4.2 Comparison of Measurements Between Non-fat-suppressed and Fat-suppressed T2-weighted MRI Sequences

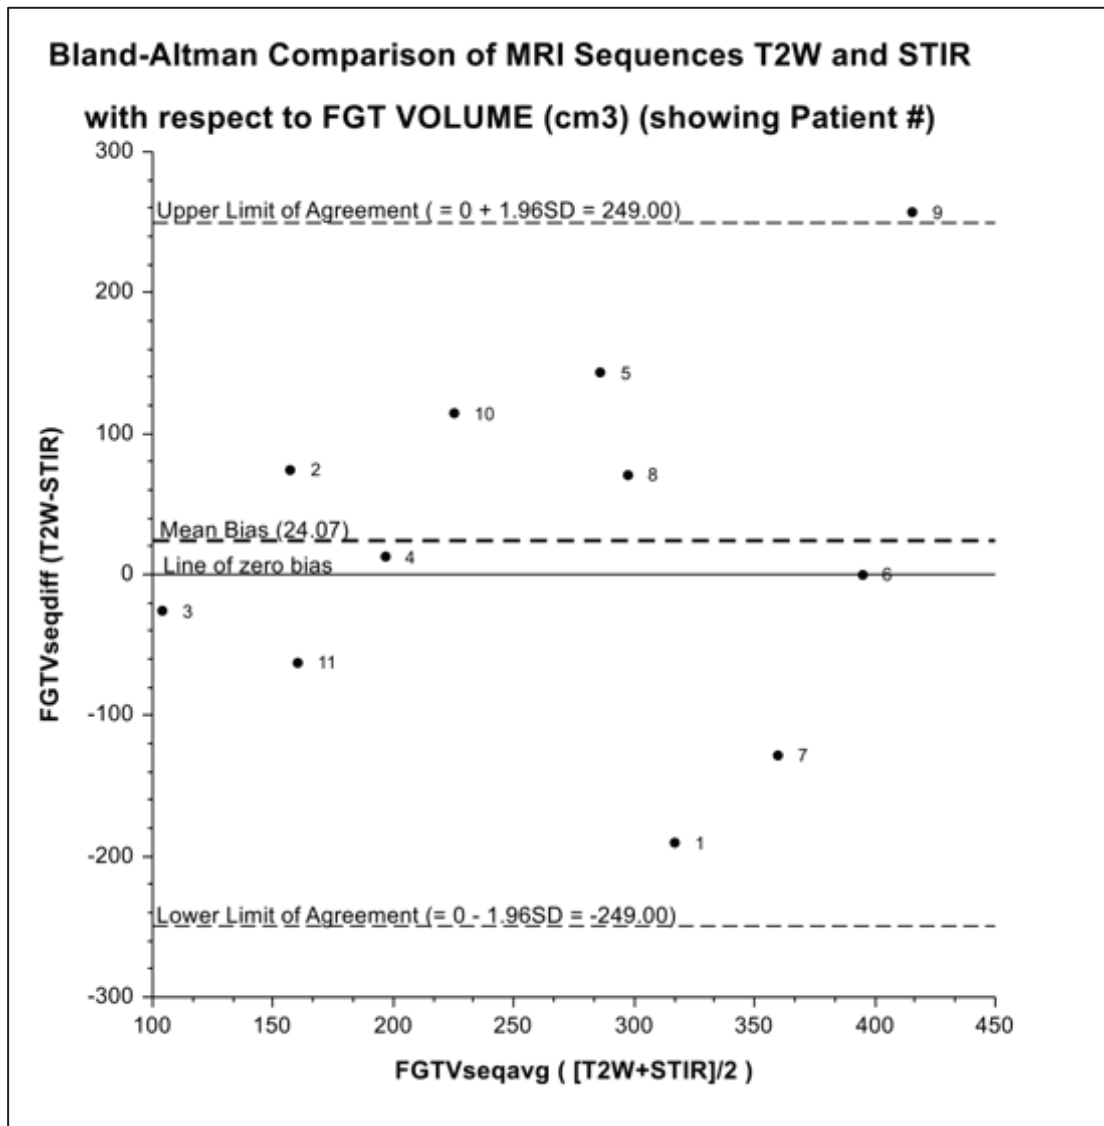

Table 5.4 lists the descriptive statistics, including mean, SD, 95% confidence interval limits, and other values for the breast density parameters. Table 5.5 demonstrates the results of the Bland-Altman analyses for breast volume, fibroglandular tissue volume, and percentage of breast density measured on the two MRI sequences, while Table 5.6 shows the tests of normality of differences assumption. Figure 5.1 plots the Bland-Altman comparison of the MRI sequences (i.e. the difference between the two MRI sequences against their average) with respect to breast density parameters. Figure 5.2 displays the degree of agreement between the non-fat-suppressed T2-weighted TSE and the fat-suppressed T2-weighted STIR MRI sequences for each of the breast density parameters.

In the whole group of 11 patients, although the breast volume measured from the non-fat-suppressed T2-weighted TSE sequence, $2745.978 \pm 1469.893 \text{ cm}^3$ (average \pm Std Dev), was lower than that of the fat-suppressed T2-weighted STIR sequence, 2885.557

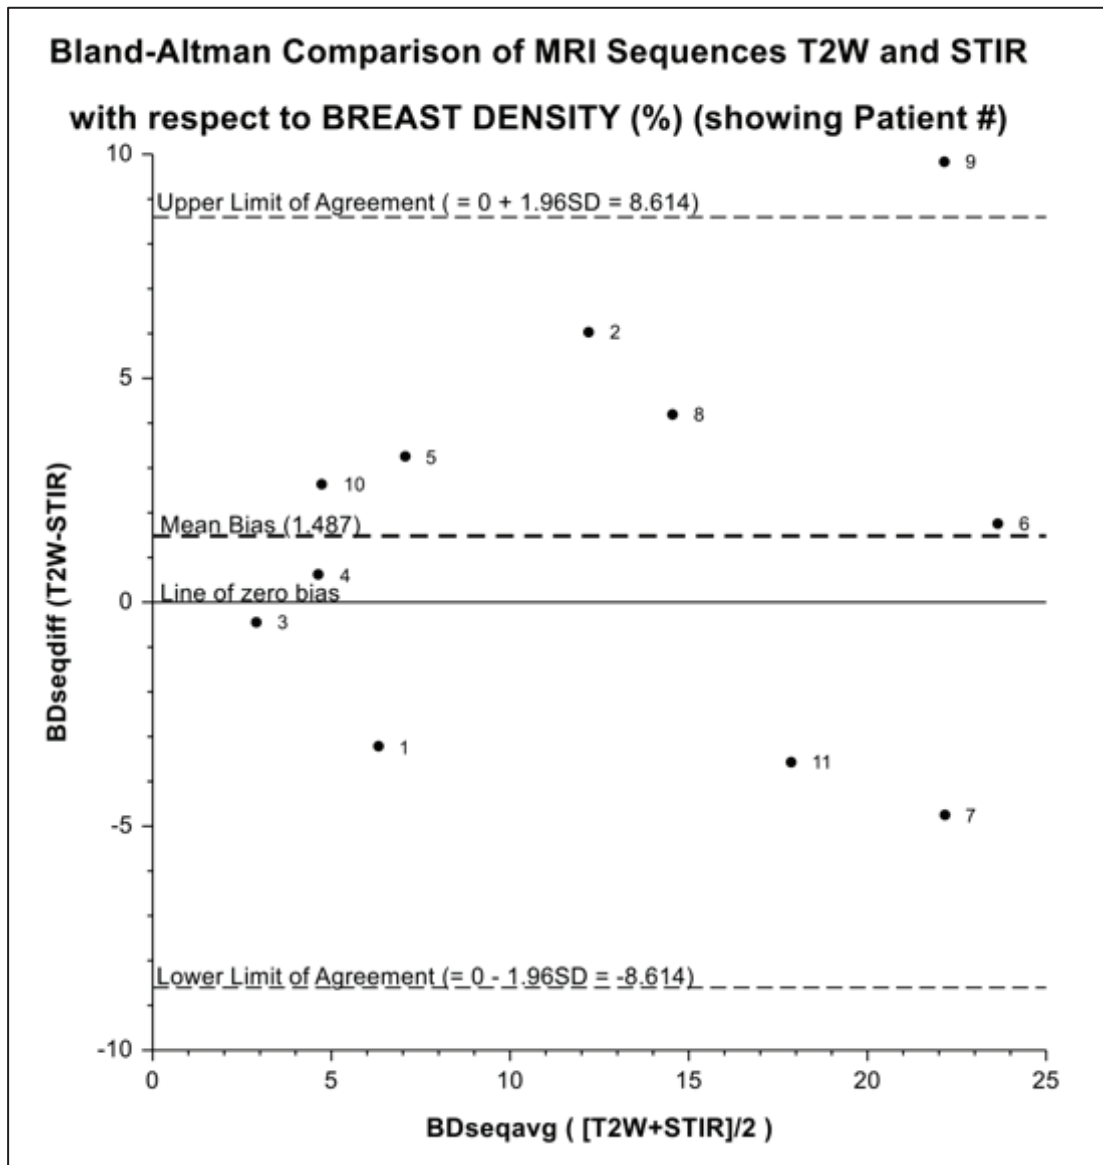

$\pm 1568.706 \text{ cm}^3$, the difference was not statistically significant ($t = -1.960, p = 0.078$), with a mean difference of $-139.579 \pm 236.191 \text{ cm}^3$ and a standard error of 71.214.

(A)

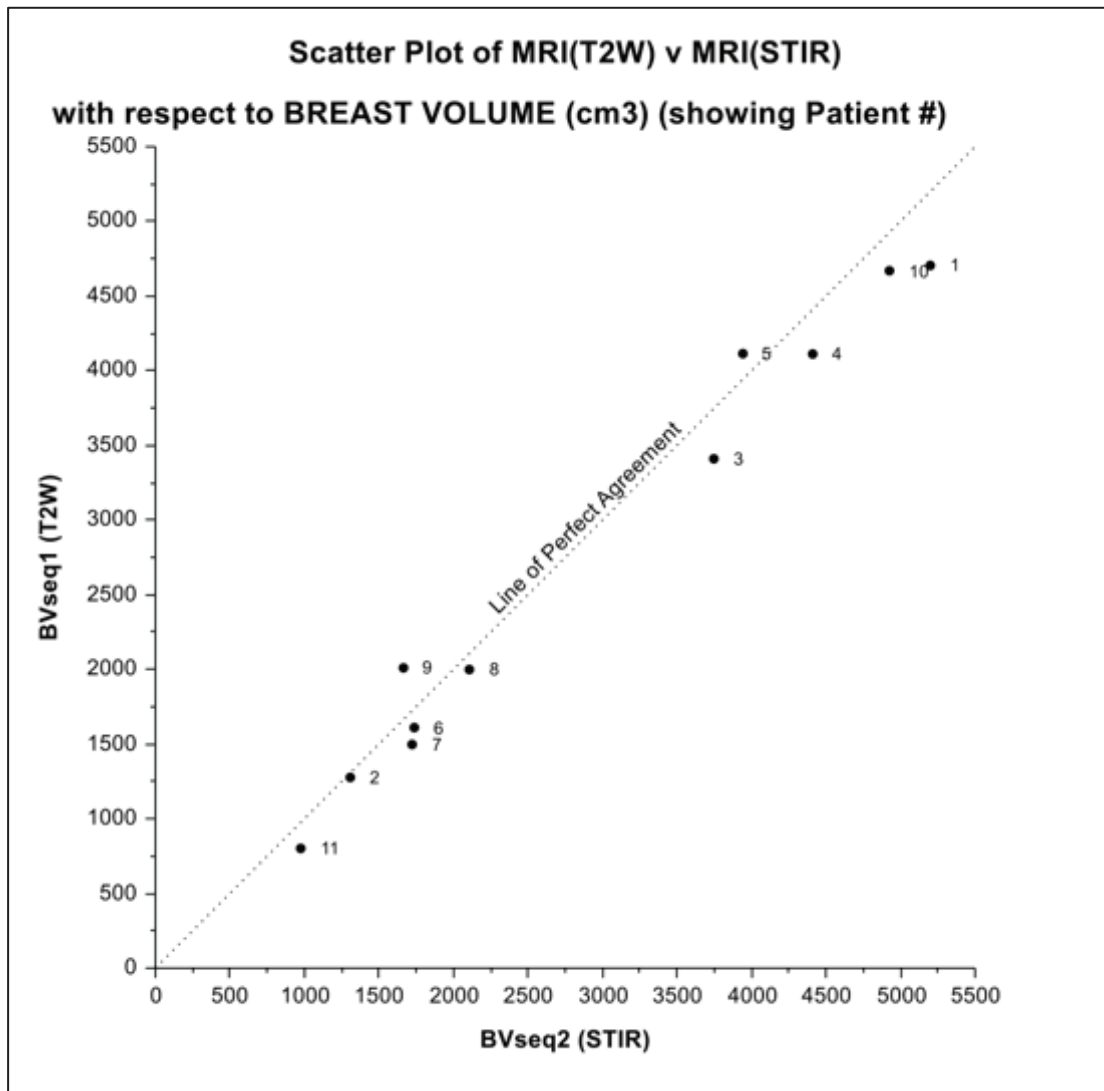

(B)

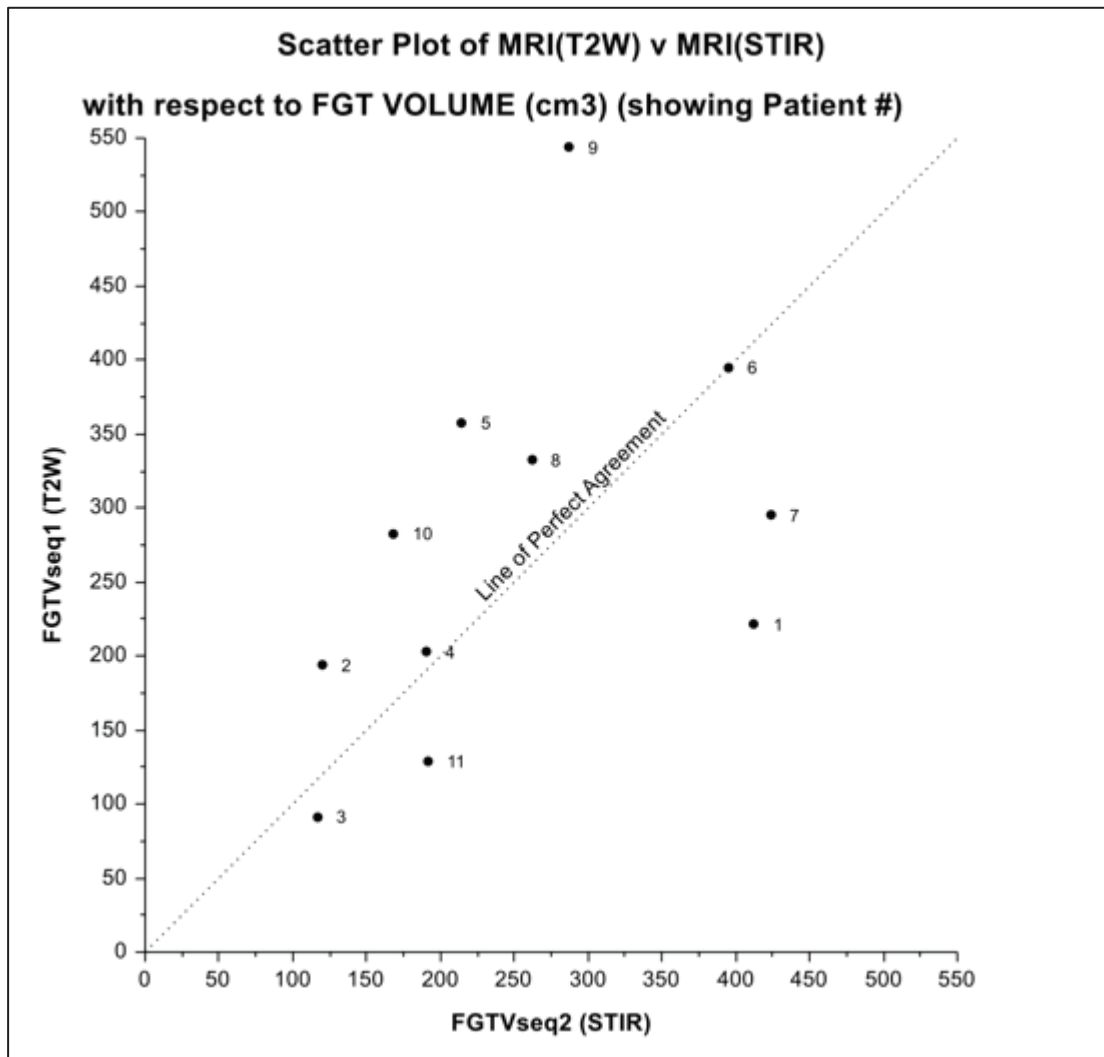

(C)

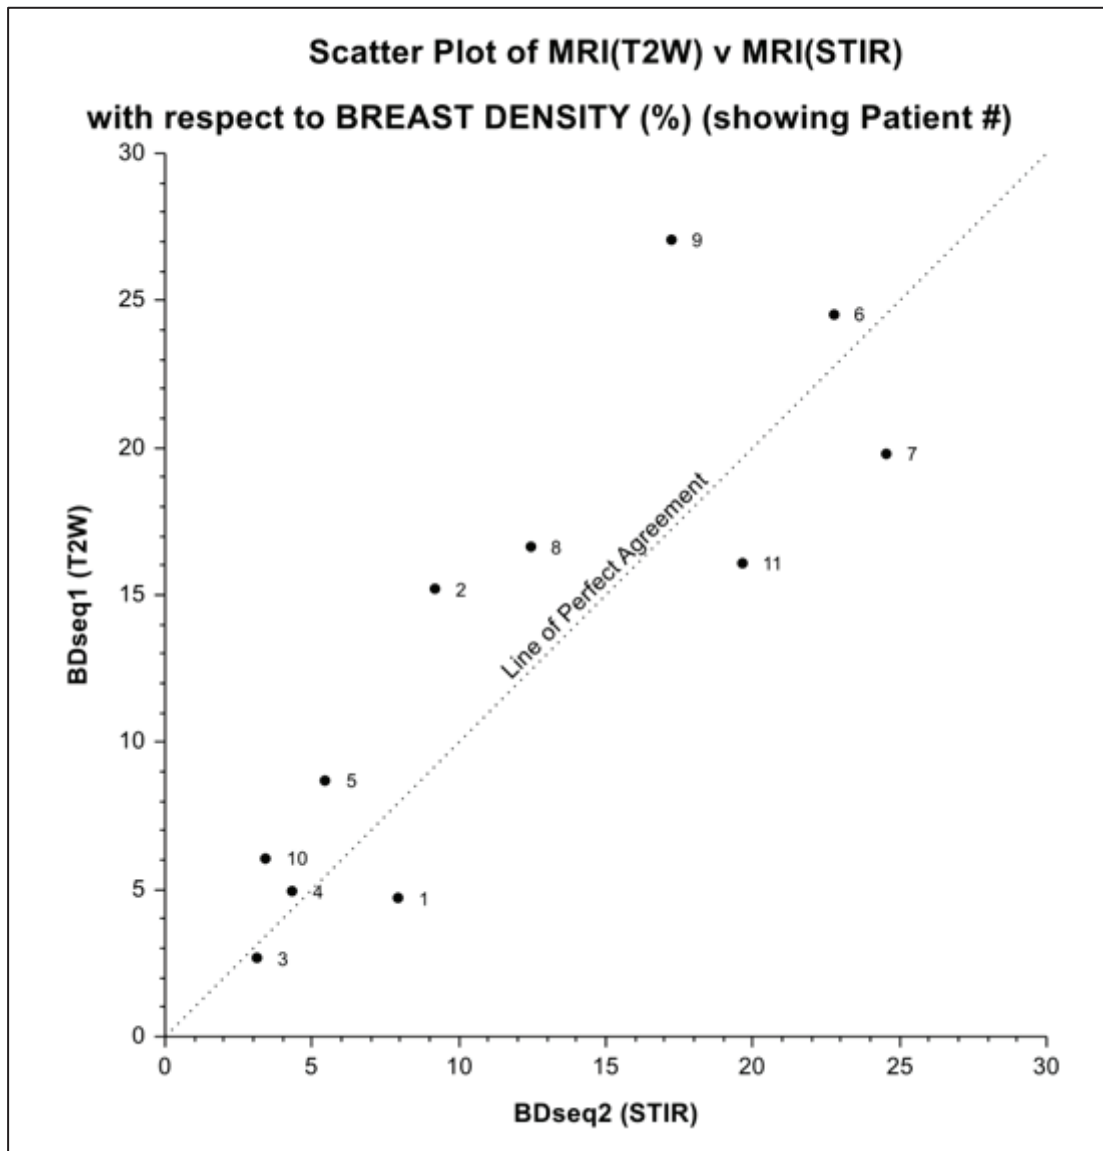

Figure 5.1. Bland-Altman plots for the breast density parameters agreement analysis (N = 11). (A) breast volume, (B) fibroglandular tissue volume, and (C) percentage of breast density measured from the non-fat-suppressed T2-weighted TSE and fat-suppressed T2-weighted STIR MR sequences. The average of the breast density parameters of the two sequences is on the x-axis, while the estimated mean difference (a measure of the bias between the two sequences) is on the y-axis. Limits of agreement are shown as solid, black lines with 95% confidence intervals (as light dotted black line), and bias (as dark dotted black line) with 95% confidence interval. Note that the limits of agreement are calculated as the mean difference \pm 1.96 Std Dev, where the Std Dev is determined from the array of difference value. The factor 1.96 indicates the assumption that the difference values are normally distributed. The upper and lower limits of the agreement 1.96 Std Dev are displayed above and below zero, not the mean difference. The differences between the two MRI sequences and their averages are listed in Table 5.3, while the Bland-Altman analyses, including the bias and limits of agreement are in Table 5.5.

(A)

(B)

(C)

Figure 5.2. Scatter plots display the degree of agreement between the non-fat-suppressed T2-weighted TSE and the fat-suppressed T2-weighted STIR MRI sequences for (A) breast volume, (B) fibroglandular tissue volume, and (C) percentage of breast density. The breast density parameters (A, B, and C) measured from the fat-suppressed T2-weighted STIR MRI sequence are on the x-axis; from the non-fat-suppressed T2-weighted TSE MRI sequence are on the y-axis. The dotted black line shows the line of equality (i.e., the line of perfect agreement); the Bland-Altman correlation of 1 indicates perfect agreement, while the value of 0 indicates complete discord. The level of agreements between the two MRI sequences are listed in Table 5.4, with a correlation coefficient of 0.990 for breast volume, 0.458 for fibroglandular tissue volume, and 0.858 for percentage of breast density.

The 95% tolerance limits of agreement were -602.513, 323.355. Likewise, there was no significant difference ($t = 0.628$, $p = 0.544$) between the volume of fibroglandular tissue measured on the non-fat-suppressed T2-weighted TSE sequence, $276.909 \pm 129.250 \text{ cm}^3$, and the fat-suppressed T2-weighted STIR sequence, $252.844 \pm 113.393 \text{ cm}^3$, with a mean difference of $24.065 \pm 127.041 \text{ cm}^3$ and a standard error of 38.304. The 95% tolerance limits of agreement were -224.935, 273.066. Further, the percentage of breast density was $13.308 \pm 8.429\%$ for the non-fat-suppressed T2-weighted TSE sequence and $11.821 \pm 7.989\%$ for the fat-suppressed T2-weighted STIR sequence, which was not statistically significant ($t = 1.122$, $p = 0.288$), with a mean difference of $1.487 \pm 4.395\%$ and a standard error of 1.325. Consequently, the fat-suppressed T2-weighted sequence appeared to result in a lower reading, by between -1.466 and 4.439 (95% confidence limits), than that of the non-fat-suppressed T2-weighted sequence. Despite this observation, the 95% tolerance limits of agreement (-7.127 and 10.101) were wide apart to give preference to one sequence over the other with respect to the quantitative measurement of breast density, as shown in Table 5.5.

The most prominent finding to emerge from the data was the comparatively high standard deviation of breast density parameters, which resulted in high individual variation among patients. However, the estimate of the standard deviations of the differences in both breast volume and breast density decreased, as some of the influence of repeated measurement error was accordingly eliminated. The results also indicated, as shown in Table 5.4, that the level of agreement between the non-fat-suppressed T2-weighted TSE and the fat-suppressed T2-weighted STIR MRI sequences had a correlation coefficient of 0.990 for breast volume, 0.458 for fibroglandular tissue volume, and 0.858 for percentage of breast density. Although the

breast volume measured on the non-fat-suppressed and the fat-suppressed T2-weighted MRI sequences was almost correlated ($r = 0.990$), as shown in Figure 5.2A, there was no evidence of agreement between the two measurement sequences.

From the data in Figure 5.1A, it is apparent that the differences in breast volume between the non-fat-suppressed and the fat-suppressed T2-weighted MRI sequences for patients 1, 3, 4, and 10 were -494.768, -337.405, -299.050, and -255.885, respectively, suggesting a rise in negative bias with increasing volumes. Nevertheless, there was a small negative bias associated with small breast volumes in patients 2, 6, and 8, with a mean difference of -31.246, -127.223, and -107.728, respectively. In contrast to breast volumes, however, there was a considerable dispersion in the volume of fibroglandular tissue and the percentage of breast density measured in the fat-suppressed and non-fat-suppressed T2-weighted sequences, as shown in Figures 5.2B and C, which made the bias more difficult to detect.

Overall, the results indicated that no evidence of measurement bias was found between the non-fat-suppressed T2-weighted TSE and the fat-suppressed T2-weighted STIR MRI sequences; furthermore, there was no proof to reject the hypothesis that the differences are normally distributed, since the majority of the mean difference is allocated between the upper and lower limits of the agreement, as shown in Figure 5.1

Table 5.2. Results of the estimated mean and standard deviation of breast volume, fibroglandular tissue volume, and percentage of breast density for high-risk women using non-fat-suppressed T2-weighted TSE (Non-fat-sup) and fat-suppressed T2-weighted STIR (Fat-sup) MRI sequences.

5.5 Discussion

Although T2-weighted imaging has been confirmed as a standard part of clinical breast MRI protocols across a variety of T2-weighted sequences, the relative role of T2-weighted images with/without the use of fat-suppression techniques in the quantitative assessment of breast density remains limited. It was hypothesized that the T2-weighted imaging features can assist in the differentiation between fibroglandular and fatty tissue, and allow for more accurate measurement of breast density. In this study, the non-fat-suppressed T2-weighted TSE and the fat-suppressed T2-weighted STIR MR imaging sequences were compared in 11 women with an increased risk of developing breast cancer with regard to their quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density. The results showed that there was no indication of measurement bias between the non-fat-suppressed and the fat-suppressed T2-weighted imaging sequences with respect to breast density parameters, and that there was no evidence to refute the presumption that the differences were normally distributed.

Although the breast volume measured in the fat-suppressed T2-weighted sequence was slightly higher than that in the non-fat-suppressed T2-weighted sequence and the difference was close to significant ($p = 0.078$), the findings showed no significant difference in the breast density parameters analyzed from the two imaging techniques. A possible explanation for these results could be that the skin is more prominent on the fat-suppressed images than on the non-fat-suppressed images; this could be the cause of such a difference in measurements, although it was considered as part of the breast volume for both sequences. Even though the signal-to-noise ratio was much higher for the non-fat-suppressed images than for the fat-suppressed images,^{44, 49} the

difference can also be explained in part by the contrast between the breast tissues and the surrounding tissues. Although it was well defined in both sequences, it could be a source of variation in the segmentation and/or measurement of breast volume and breast density outcomes. A previous study showed that the breast volume, fibroglandular tissue volume, and percentage of breast density measured in the T1-weighted sequences with and without fat-suppression techniques are highly correlated.⁴⁴ Although these results differed from the current study, which specified that the breast density parameters were quantified on the T1-weighted images, they are consistent with our findings, which showed that the breast volumes measured on the non-fat-suppressed and the fat-suppressed sequences were almost identical.

As the quantification of breast density parameters was based on different density prototypes, the findings showed that the difference in breast volume between the non-fat-suppressed and the fat-suppressed T2-weighted MRI sequences could be classified into two patterns: the first indicates small negative differences associated with small volumes, while the second indicates large negative differences associated with large volumes, as shown in Figure 5.1A. This clustering in both the non-fat-suppressed and the fat-suppressed T2-weighted sequences suggests that a systematic effect may be a reason for this rather than a random variation. However, the volume of fibroglandular tissue and the percentage of breast density measured in both sequences were noticeably dispersed, making the bias more difficult to detect, as shown in Figures 5.1B and C. It is possible, therefore, that the segmentation method of the breast volume and fibroglandular tissue volume may have been affected by the variation of the subject, although this needs to be confirmed by future research.

Another important finding arising from this study was that the percentage of breast density measured on the non-fat-suppressed T2-weighted sequence was subsequently increased compared to the fat-suppressed T2-weighted sequence because of the increased fibroglandular tissue volume and decreased breast volume. The assessment of breast density varies with pulse sequence, image quality, and fibroglandular tissue segmentation. This may result in a profound effect on the efficiency of the segmentation and/or measurement method and consequently on the results of breast density parameters. The segmentation and/or measurement of breast density parameters could be affected by the various levels of inhomogeneity in both the fat-suppressed and non-fat-suppressed MR images. The difference could also be attributed to the fact that breast MRI is obtained with a surface coil covering a wide region, which results in varying signal strength depending on the location of the tissue being imaged.

While this study reported that no substantial difference was observed between the non-fat-suppressed and the fat-suppressed T2-weighted imaging sequences for the quantitative measurement of breast density parameters, the findings are subject to certain limitations. First, the type of fat suppression used in this study relied on an inversion-based approach, which is just one of several methods; caution must be used, as it might not be possible to extrapolate the results to all fat-suppression techniques. Second, although the acquisition of the non-fat-suppressed and fat-suppressed sequences was based on a two-dimensional imaging, the scanning parameters, such as field-of-view and matrix size, were relatively different; this may play a role in the segmentation and/or measurement of breast density; however, caution should be applied because the results may not be applicable to clinical practice without further investigations. Further research to examine the impact of the scanning/technical parameters on the quantitative measurement of breast density would be suggested.

Third, the association of breast density parameters and the T2-weighted imaging sequences could not be further explored, as the sample size was limited. It must be acknowledged that the small sample size was selected because of the expected complexity of recruiting cancer-free patients at high risk of developing breast cancer. Nevertheless, a further study with a larger sample size to determine exactly how the non-fat-suppressed and fat-suppressed T2-weighted sequences influence the quantification of breast density would be desirable. Further, the study is limited by the lack of information about the patient age; this may highlight the potential correlation between age dependency and the results, thus explaining the disparity between the two MRI sequences with respect to the patterns of breast density parameters, because the distribution of fibroglandular tissue varies from age to age and from person to person. Finally, using a semi-automated method, the breast density parameters were segmented and measured; this means that the prospective cause of such a discrepancy between the non-fat-suppressed and fat-suppressed sequences could be due to a high degree of reliance on user interaction. In future studies, it might be possible to use deep learning method to segment breast and fibroglandular tissue,^{50, 51} in which the degree of difference between the non-fat-suppressed and fat-suppressed T2-weighted imaging sequences could be more accurately assessed with regard to the quantitative measurement of breast density in MRI volumes.

5.6 Conclusion

Of the two types of scanning techniques used in this study, there seems to be no substantial difference between the non-fat-suppressed and fat-suppressed MR pulse sequences for the quantitative measurement of breast density parameters; however, a

much larger study is required to determine the complementary role of T2-weighted imaging in this regard.

6. Chapter 6

Conclusions and Future Directions

6.1 Conclusions

This study was performed to investigate the quantitative assessments of breast density using breast MR imaging protocols with the aim of determining the optimal breast MRI protocol. Through both phantom experiments and clinical data analysis, expected outcomes are achieved with significant findings as reported below.

A systematic review and meta-analysis study was conducted to evaluate the existing research on quantitative assessment of breast density using MRI data. This was the first comprehensive systematic review and meta-analysis of pooling the results of 38 studies reporting all breast density segmentation/measurement methods and scanning protocols using MRI data. Results of the analysis are summarised as follows:

- The review confirmed high levels of heterogeneity within the breast density studies, primarily due to the applications of MR breast-imaging protocols and the use of breast density segmentation/measurement methods.
- The study revealed that the assessment of breast density varied with pulse sequence, image quality, and fibroglandular tissue segmentation. This may result in a profound effect on the efficiency of the segmentation and/or measurement method and consequently on the results of breast density parameters.
- The analysis confirmed that the non-contrast-enhanced T1-weighted acquisition was commonly utilized among all MR breast-imaging protocols and the FCM is the most frequently used algorithm amongst the breast density segmentation/measurement methods.

This research successfully identified the appropriate materials for simulating the MRI related-characteristics of fibroglandular and adipose breast tissues, and developed a personalized 3D-printed breast model using 3D-printing techniques and tissue mimicking materials for the assessment of breast density. Outcomes are stated as follows:

- Anthropomorphic shapes of skin and fibroglandular tissues were constructed using 3D-printing techniques based on the segmentations of breast MR images from a selected healthy patient's data.
- All the 3D skin and fibroglandular region shells were designed as hollow structures using polylactic acid and photopolymer resin.
- The silicone and peanut oils were found to closely resemble the T1 relaxation times and imaging characteristics of fibroglandular and adipose breast tissues, respectively.
- The phantom was used to test different breast MR imaging protocols to determine the optimum scanning parameters for the quantitative assessment of breast density.

The breast density parameters were quantitatively assessed using a personalized 3D-printed breast model and an objective comparison between the non-fat-suppressed and fat-suppressed MRI sequences. Findings are summarised as follows:

- The volume of fibroglandular tissue and the percentage of breast density were significantly higher in the fat-suppressed sequences than in the non-fat-suppressed sequences; however, the difference in breast volume was not statistically significant.

- The fat-suppressed sequences tended to be more useful than the non-fat-suppressed sequences for the quantitative measurements of the volume of fibroglandular tissue and the percentage of breast density.
- A fat-suppressed T2-weighted with turbo inversion recovery magnitude (TIRM) imaging sequence was superior to the non-fat- and fat-suppressed T1- and T2-weighted sequences for the quantitative measurement of breast density due to its ability to represent the exact breast tissue compositions.
- The segmentation and/or measurement of breast density parameters could be affected by the various levels of inhomogeneity in both the fat-suppressed and non-fat-suppressed MR images.
- The difference could also be attributed to the fact that breast MRI is obtained with a surface coil covering a wide region, which results in varying signal strength depending on the location of the tissue being imaged.

Finally, the breast density parameters were quantitatively assessed in a cohort of high-risk women based on an objective comparison between the fat-suppressed and non-fat-suppressed T2-weighted MRI. Key findings are stated as follows:

- The results revealed no indication of measurement bias between the non-fat-suppressed and fat-suppressed T2-weighted imaging sequences with respect to breast density parameters, and no evidence to reject the presumption that the differences were normally distributed.
- Although the breast volume measured in the fat-suppressed T2-weighted sequence was slightly higher than that in the non-fat-suppressed T2-weighted sequence and the difference was close to significant, the findings showed no

significant difference in the breast density parameters analyzed from the two imaging techniques.

- This study showed no substantial differences between the non-fat-suppressed and fat-suppressed T2-weighted imaging sequences in the quantitative measurement of breast density parameters; however, further studies with inclusion of a larger sample size are required to validate the complementary role of T2-weighted imaging in this regard.
- Although the acquisition of the non-fat-suppressed and fat-suppressed sequences was based on a two-dimensional imaging, the scanning parameters, such as field-of-view and matrix size, were relatively different; this may play a role in the segmentation and/or measurement of breast density, and therefore in the results.
- The type of fat suppression used in this study relied on an inversion-based approach, which is just one of several methods; caution must be used, as it might not be possible to extrapolate the results to all fat-suppression techniques.

6.2 Future Directions

This research has intensified the need for a standardized imaging protocol and/or measurement method for the evaluation of breast density predominantly for women at an elevated risk of developing breast cancer, for those with high breast density. The study showed how 3D-printing techniques and tissue mimicking materials can be used to construct a customized breast model for the quantitative assessment of breast density. The findings also indicate that the silicone and peanut oils can effectively

mimic the T1 relaxation times and MR imaging characteristics of fibroglandular and adipose breast tissues. The proposed methodologies can be used as a preliminary work for breast structure simulations and the development of further patient models based on MRI datasets.

Although the fat-suppressed sequences were more useful for the quantitative measurements of the volume of fibroglandular tissue and the percentage of breast density in a patient-specific 3D-printed breast model than the non-fat-suppressed sequences, this work was limited by the fact that breast density parameters were segmented and measured using a semi-automated method, which indicates that the prospective cause of such a difference between the aforementioned imaging sequences could be due to a high degree of reliance on user interaction.

A fat-suppressed T2-weighted with TIRM imaging sequence was superior to the non-fat- and fat-suppressed T1- and T2-weighted sequences for the quantitative measurement of breast density due to its ability to represent the exact breast tissue compositions. Despite being preliminary findings, the study indicates that TIRM could be incorporated with fat-suppression techniques for the assessment of breast density. The fat-suppressed T2-weighted image with TIRM acquisition can be a promising technique for the quantitative assessment of breast density, although further research should be conducted to verify this suggestion. Despite the fact that there were no substantial differences between the non-fat-suppressed and fat-suppressed T2-weighted imaging sequences for the quantitative measurement of breast density parameters in a cohort of high-risk women, the study's findings are constrained by the small sample size.

Many questions and potential research directions have emerged as a result of this study, which would need to be investigated further. Some suggestions for future research are as follows:

- 3D-printed breast models can be used to guide breast reconstructive surgery to improve clinical outcomes. This can be enhanced further by the use of a variety of customized breast implants in different shapes and sizes.
- A more realistic breast phantom with different amounts of breast composition could be created using 3D-printing technique and tissue mimicking materials. This can correspond to the four categories of the ACR BI-RADS atlas, allowing an estimation of the volume of fibroglandular tissue, and thus breast density.
- Another possible area of future research would be to examine more closely the observed correlations between silicone oil's T1 relaxation time and fibroglandular tissue.
- Multiple MR breast-imaging protocols are suggested, not only to measure the breast density but also to assess the impact of implementing various image quality parameters (i.e., FOV, matrix size and slice thickness) on the segmentation/measurement of breast density.
- More research would be required to evaluate the Analyze 14.0 software's effectiveness in the segmentation/measurement of breast density, especially in the differentiation between fibroglandular and fatty tissues.
- A further study with a larger sample size would be desirable to determine exactly how the non-fat-suppressed and fat-suppressed T2-weighted imaging sequences influence the quantification of breast density, and thus allowing more robust conclusions to be drawn.

- Deep learning methods may be used to segment breast and fibroglandular tissue, in which the degree of difference between the non-fat-suppressed and fat-suppressed imaging sequences could be more accurately assessed in terms of the efficiency and accuracy of quantitative measurement of breast density in MRI volumes.

Abstract: Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, is confirmed as an independent risk factor of breast cancer. Although there has been an increasing interest in the quantitative assessment of breast density, no research has investigated the optimal technical approach of breast MRI in this aspect. Therefore, we performed a systematic review and meta-analysis to analyze the current studies on quantitative assessment of breast density using MRI and to determine the most appropriate technical/operational protocol. Databases (PubMed, EMBASE, ScienceDirect, and Web of Science) were searched systematically for eligible studies. Single arm meta-analysis was conducted to determine quantitative values of MRI in breast density assessments. Combined means with their 95% confidence interval (CI) were calculated using a fixed-effect model. In addition, subgroup meta-analyses were performed with stratification by breast density segmentation/measurement method. Furthermore, alternative groupings based on statistical similarities were identified via a cluster analysis employing study means and standard deviations in a Nearest Neighbor/Single Linkage. A total of 38 studies matched the inclusion criteria for this systematic review. Twenty-one of these studies were judged to be eligible for meta-analysis. The results indicated, generally, high levels of heterogeneity between study means within groups and high levels of heterogeneity between study variances within groups. The studies in two main clusters identified by the cluster analysis were also subjected to meta-analyses. The review confirmed high levels of heterogeneity within the breast density studies, considered to be due mainly to the applications of MR breast-imaging protocols and the use of breast density segmentation/measurement methods. Further research should be performed to determine the most appropriate protocol and method for quantifying breast density using MRI.

Keywords: Magnetic resonance imaging; breast density; fibroglandular-tissue; systematic review and meta-analysis; cluster analysis; segmentation; FCM; breast-imaging protocol; non-contrast-enhanced T1-weighted

1. Introduction

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, is an independent risk factor for breast cancer [1–3]. Consistent with this risk relationship, women who

have dense breasts have a likelihood of developing breast cancer that is fourfold higher than those with fatty breasts [4,5]. Most of the information regarding breast density has been acquired with two-dimensional imaging, which is mammography. However, the evaluation of breast density based on mammograms is limited due to the overlapping of tissues, variations in breast compression, and inappropriate positioning that lead to artefacts (skin folder) and inclusion of insufficient breast tissue [6,7]. These factors could affect mammography's performance for precise, reliable measurements of small changes in breast density over brief timespans [8,9].

Magnetic resonance imaging (MRI), an alternative imaging modality in breast imaging can estimate the actual breast density value because it provides a three-dimensional volume assessment of breast tissue, with excellent contrast resolution in the differentiation between fibroglandular and fatty tissues [10–13]. Conventionally, breast density is assessed qualitatively using the American College of Radiology (ACR) Breast Imaging-Reporting and Data System (BI-RADS) atlas, which is a classification system commonly used for mammography, according to which density has four categories based on the amount of fibroglandular tissue: “(1) almost entirely fat, (2) scattered fibroglandular tissue, (3) heterogeneous fibroglandular dense and (4) extreme fibroglandular tissue” [14,15]. The interpretations of these four categories are also applied for MRI. Despite its long clinical success, the BI-RADS scoring atlas is subjective and varies between readers, even within the same reader [16]. To overcome a subjective assessment of breast density and to reduce inter- and intra-reader variability, different methods for quantitative breast density have been proposed, with a range of algorithms or methods reported in the literature [17–22]. Each of these methods were shown to have advantages and limitations through the use of semi-automatic thresholding and segmentation approaches for quantitative assessment of breast density.

There is no doubt that MRI is one of the most useful modalities for breast imaging and that the analysis of breast density in quantitative synthesis is a well-established approach. In spite of the fact that extensive research has been carried out on breast density measurements, no consensus has been reached about the optimal approach to quantify breast density using MRI. Therefore, the purpose of this review is to analyze the current methods for the quantitative assessment of breast density using MRI over the past decade of publications. Due to the expected heterogeneity of MRI scanning protocols, both systematic review and meta-analysis were performed to analyze the available studies.

2. Materials and Methods

This systematic review and meta-analysis were performed according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) criteria [23,24]. No ethics committee approval was required.

2.1. Search Strategy and Eligibility Criteria

A systematic literature review was conducted of studies that analyzed breast density in a quantitative pattern using MRI. Briefly, a search for studies published between 1 January 2009 and 31 December 2018 was conducted in different databases: PubMed (MEDLINE, U.S. National Library of Medicine and National Institutes of Health, Bethesda, MD, USA), EMBASE (Elsevier, Amsterdam, The Netherlands), ScienceDirect (Elsevier, Amsterdam, The Netherlands), and Web of Science (Clarivate Analytics, Philadelphia, PA, USA) using the search terms detailed below.

Systematic search expressions were employed using MeSH (medical subject headings) in PubMed and the thesaurus in EMBASE, ScienceDirect, and Web of Science. A search structure was based on combining three main terms as follows: “breast density,” “quantitative analysis,” and “MRI.” The exact search expressions were “Breast Density” (MeSH term) OR “fibroglandular tissue” (Text word) OR “breast densit*” (Text word) OR “FGT” (Text word) OR “FT” (Text word) OR “fibroglandular densit*” (Text word) AND “Quantitative analysis” (Subject heading) AND “Magnetic Resonance Imaging” (MeSH term) OR “nuclear magnetic resonance imaging” (Text word) OR “MRI” (Text word) OR “magnetic resonance imaging” (Text word). The criteria for selecting the studies for eligibility were based on their title, abstract, and subsequently the full text, this was performed independently by two reviewers (R.S. and Z.S.). Studies addressing the quantitative

analysis of breast density using MRI were considered eligible for inclusion and also studies on human subjects since 2009 had to be published in peer-reviewed journals and written in English. For study inclusion, the subjects must have undergone breast MRI studies and the breast density measurement method is known. Eligible studies were retrieved, and full manuscripts were read. No restricted conditions have been applied in terms of study characteristics, the purpose of study, and the results. Publications were only included in the analysis if the measurement of breast density had been performed in a quantitative manner regardless of the MRI technique or breast density segmentation/measurement method.

2.2. Data Extraction

On completing the eligibility screening, the process of data extraction from the included studies was carried out manually by the same two reviewers. Descriptive data were extracted for all variables as follows: the first author's surname; year of publication; journal of publication; study type; total number of participants/patients; mean age; age range of participants/patients; MRI technique (pulse sequence/breast-imaging protocol and static magnetic field strength); and breast segmentation/measurement method. For each study analyzed, estimates of breast volume, fibroglandular-tissue volume and percentage breast density were recorded using descriptive statistics, arithmetic means and standard deviations, whenever appropriate. Due to the heterogeneous nature of this analysis, some of the included studies produced their results in a median and interquartile range (IQR). Accordingly, the researchers decided to stratify results and excluded them from the meta-analysis only.

2.3. Data Synthesis

The combinations of MRI techniques and the applied breast segmentation/measurement methods encountered in the studies were considered to be technologically heterogeneous. To address this issue and acquire more reasonable estimates, the analyses were stratified by breast segmentation method into three discrete groups (fuzzy c-mean clustering (FCM), FCM and nonparametric nonuniformity normalization (N3), and signal intensity thresholding). In each sub meta-analysis, the number of the included studies were selected on the basis of a degree of homogeneity of their breast density segmentation/measurement results.

2.4. Statistical Analysis

The measurement of breast density as ascertained by MRI using semi- or fully-automated segmentation method was assessed. The primary outcome was the percentage breast density (%BD). Data input for each study within a group consisted of the study size (N), the 'raw' study mean (i.e., with no re-scaling or standardization), and the study standard deviation. The data was analyzed by the "metamean" function in the "meta" package in the R system, Version 3.4.1 (<http://www.r-project.org/>). This facilitates the meta-analysis of a single arm trial, as opposed to the traditional two arm trial with a control group and a treatment group, equivalent to a one-way analysis of variance. A forest plot was generated, displaying the individual study (%BD) means with 95% confidence interval (CI) limits, inverse variance study weights, and the pooled mean and confidence limits. Heterogeneity of study means was assessed using Cochran's Q-test, and heterogeneity of study variances was assessed with Bartlett's test. A conclusion to pool studies requires both heterogeneity tests to be non-significant at the 5% level.

As an alternative to grouping the studies on a technological basis, a cluster analysis was run to investigate any similarities between studies with respect to two attributes, namely study mean and study standard deviation. The International Business Machines Statistical Package for the Social Sciences (IBM SPSS) Statistics software Version 25.0 was used for cluster analysis. The procedure provides for a wide selection of combinations of distance measures and clustering methods, but for the current application, the simplest of these was chosen, namely Euclidean distance and nearest neighbor agglomeration. This algorithm calculates a proximity matrix of distances between all

possible pairs of studies and allocates the closest pair into a cluster, then examines the remaining clusters to identify which is the next nearest or whether there is a pair that are closer to one another, and so on.

3. Results

3.1. Literature Search

Figure 1 presents an overview of the systematic search of the literature through different databases. The complete search yielded 941 studies. After removing duplicates (n = 70), 871 were screened, based on their titles, which resulted in 765 being excluded, followed by 27 of the remaining studies being excluded on the basis of their abstracts. Of the remaining 79 studies, the full manuscript was retrieved and reviewed. Forty-one studies did not meet the selection inclusion criteria: no adequate breast density data (n = 20), qualitative analysis (n = 12), editorials (n = 4), conference abstracts (n = 3), post-mortem study (n = 1), and phantom study (n = 1). Finally, 38 studies attained the inclusion criteria [1–3,5,11,25–57] and were included in the analysis as shown in Table 1.

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) flowchart of systematic review and meta-analysis of the excluded and included studies.

3.2. Systematic Review

Table 1 demonstrates some of the main characteristics of the 38 included studies, while Figure 2 shows details of the study design and MRI system used in these studies. Several MRI sequences were used to enable the precise differentiation between adipose and fibroglandular tissues; of these, non-contrast-enhanced T1-weighted was widely used either with 2D spin echo or 3D gradient echo. In fact, 16 studies (41.03%) used non-contrast-enhanced T1-weighted [1,2,26–29,31,33,35,44,45,48–51,53], while in 12 studies (30.77%) non-contrast-enhanced images were integrated with contrast-enhanced images [25,36–44,47,49]. In terms of breast density segmentation/measurement, the majority of the studies (20 studies; 51.28%) used FCM clustering algorithm [1,2,11,25–29,31–42], while 7 studies (17.95%) used FCM and N3 algorithm [45–51], 4 studies (10.26%) interactive thresholding algorithm [3,5,52,53], 4 studies (10.26%) in-house customized software [29,53–55], one study (2.56%) manual software [57]; however, two studies did not provide the information [43,44].

Among the thirty-eight studies included in the systematic review and meta-analysis, 21 studies qualified for meta-analysis since they reported the percent breast density using an identical expression of measurement and dispersion [1,3,11,25–32,36–38,45,48–50,53–55] (Table 2). However, for the remaining 17 studies, the percent breast density was reported in different format: in eight of these studies, it was defined as a median and interquartile range (IQR) [2,39–44,47], and in the other nine, it was reported either in different measurement unit or the subject’s sets were not independent, due to multiple usage [5,33–35,46,51,52,56,57]. To perform the meta-analysis precisely, all the measured quantities should be reported in an identical expression of measurement and dispersion, thus we decided to exclude them from the meta-analysis.

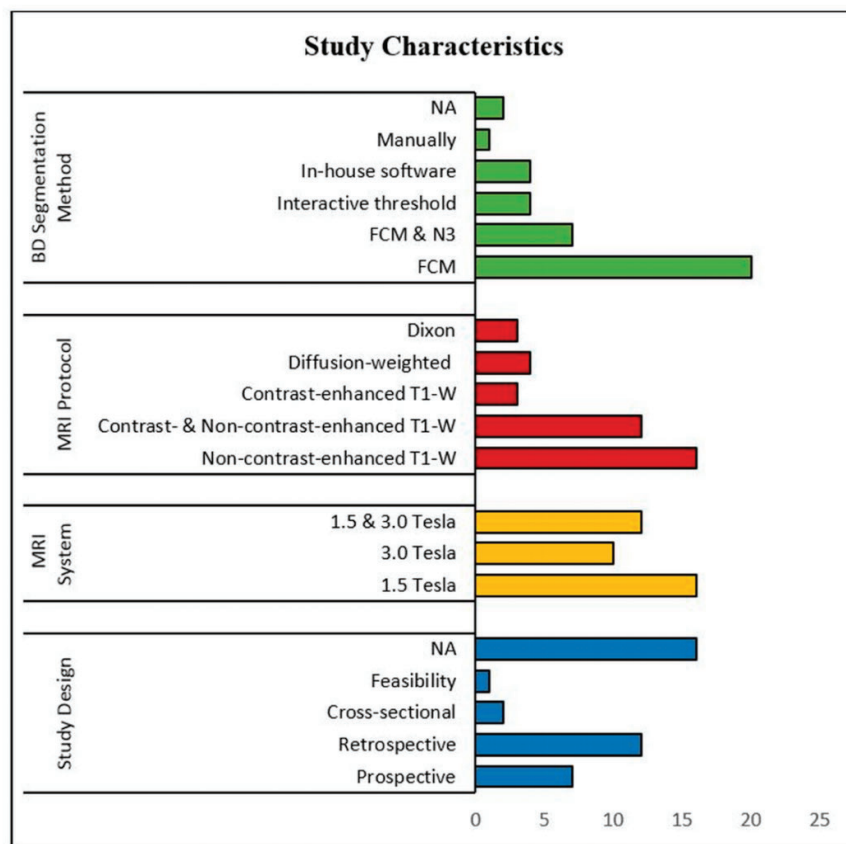

Figure 2. Flowchart of the study characteristics (study design, MRI system, MRI sequence, Breast Density (BD) segmentation method) of 38 studies.

3.4. Subgroup Analyses

The final inclusion consisted of a total of twenty-one studies in the meta-analyses; the forest plots and pooled results are shown in Figure 3.

(E) Fixed effect meta-analysis of the semi-automated threshold group of studies of % breast density.

3.4.1. Fuzzy C-mean Clustering (FCM)

The FCM subgroup consisted of 13 studies, of which, 10 studies reported breast density as a percentage breast density (% BD) [1,11,25–32], whereas 3 studies as a percentage of the dense breast volume (% DBV) [36–38]. On one hand, 10 studies with inclusion of 634 patients were included, as Figure 3A shows, there is a wide range of mean values as well as standard deviation (SDs) from those studies, which indicated enormous heterogeneity among study means (Cochran's Q test: $X^2 = 86.93$, $P < 0.0001$). Indeed, there is a substantial heterogeneity among study variances (Bartlett's test: $X^2 = 110.59$, $P < 0.0001$). On the other hand, three studies with inclusion of 528 patients were analyzed. Figure 3B shows there is a high level of homogeneity among study means (Cochran's Q test: $X^2 = 0.13$, $P = 0.94$), and a high level of homogeneity among study variances (Bartlett's test: $X^2 = 0.12$, $P = 0.94$), which would be expected as those studies used an identical combination of MR technique and breast density segmentation/measurement approach.

3.4.2. FCM and Nonparametric Nonuniformity Normalization (N3)

The FCM and N3 subgroup included 4 studies with inclusion of 126 patients [45,48–50], as Figure 3C shows, there is a wide range of mean values as well as SDs from those studies, which indicated tremendous heterogeneity among study means (Cochran's Q test: $X^2 = 99.94$, $P < 0.0001$). Indeed, there is a substantial heterogeneity among study variances (Bartlett's test: $X^2 = 45.41$, $P < 0.0001$), which would be expected as those studies used different MR breast-imaging protocols.

3.4.3. Interactive Semi-Automated Threshold

Two studies [3,54] comprising of 58 patients were included in the analysis, which indicated a considerable heterogeneity among study means (Cochran's Q test: $X^2 = 10.26$, $P = 0.0014$). In contrast, there was no evidence of heterogeneity among study variances (Bartlett's test: $X^2 = 1.61$, $P = 0.2072$).

On the other hand, two studies with inclusion of 67 patients [53,55] were analyzed as shown in Figure 3E, there was no evidence of heterogeneity among study means (Cochran's Q test: $X^2 = 3.01$, $P = 0.0825$), which would be expected as those studies used the same MRI technique and breast density measurement. However, there is a substantial heterogeneity among study variances (Bartlett's test: $X^2 = 18.84$, $P < 0.0001$).

3.5. Cluster Analysis

The results obtained from the clustering analysis "Dendrogram using Single Linkage" are shown in Figure 4. From this data, it can be seen that a hierarchical diagram showing various distances (0–25) at which studies joined various groups. On that basis, six clusters were identified. A list of cluster membership, study means, SDs, and coefficient of variations (CVs) (expressed as a percentage) is shown in Table 3. A scatter plot of the study means versus SDs is shown in Figure 5, the legend in the scatter plot indicates the number of studies in each cluster. Cluster markers with solid fill indicate clusters with two or more studies, whereas open markers indicate singletons. Cluster 1 included nine studies that analyzed breast density with a combination of contrast and non-contrast T1-weighted either with 2D spin echo or 3D gradient echo; however, Choi [49] used diffusion-weighted scanning technique. From the data in Table 3 (Cluster 1), it is apparent that the CVs are varied in value, but in Choi's study [49] the CV is almost 100% because of the mean and SD are almost identical. In contrast, the CVs for Chan [48] and Chen [53] are much lower than the rest of the included studies, largely

because of the small SDs and the breast segmentation methods being used which are FCM and N3 and interactive semi-automated threshold algorithms, respectively.

Figure 4. Dendrogram clustering analysis using “Single Linkage” method of the study means, and study SDs among 21 included studies in the subgroup meta-analyses.

Table 3. Study size (N), mean, SD, coefficient of variations (CV), and cluster membership of the included studies.

In contrast, cluster 2 consisted of 8 studies that assessed breast density with a combination of contrast- and non-contrast-enhanced T1-weighted with 3D gradient echo, however, Chen [31] and Chen [45] used non-contrast- and contrast-enhanced T1-weighted with 2D spin-echo, respectively. Indeed, Chen [45] analyzed breast density using FCM and N3 algorithms. From the data in Figure 5

and Table 3 (Cluster 2), it is apparent that the CVs are almost within a closed range except for Chen [45] where the CV is much lower than the remaining studies because of the small SD and the breast segmentation method that previously mentioned. Also, Wengert [55] used Dixon method as a technical protocol for breast-imaging, although they measured the breast density using in-house customized software, the mean and SD are not different to the other included studies. The most striking result to emerge from the data in Figure 5 and Table 3 (Cluster 3–6) is the Chen [1] study (i.e., Cluster 3), although it used non-contrast-enhanced T1-weighted with 3D gradient echo and analyzed breast density by FCM algorithm, the CV (11.67%) is much lower than the remaining studies, mainly because of the small SD.

Cluster 4 included two studies Chan [48] and Chen [50] that assessed breast density using FCM and N3 algorithms and non-contrast-enhanced T1-weighted with 3D gradient echo. As can be seen from the data in Figure 5 and Table 3 (Cluster 3–6) the study means and SDs are not different. In contrast to this Cluster 5, the Tagliafico study [3] used 3D contrast-enhanced T1-weighted gradient echo sequence and analyzed the breast density by semi-automated interactive threshold, in particular, (MedDensity). As Figure 5 and Table 3 (Cluster 3–6) show, the study mean is much higher than the remaining studies, largely because of the technical method used. Finally, cluster 6 consisted of Lodger [54], this is the only study that used proton density weighted sequence. Detailed information of clustering membership, study means, SDs, and CVs is shown in Table 3, Figures 4 and 5.

Switching from technology groupings of studies to groupings identified by the cluster analysis, meta-analysis of cluster 1 revealed that the study means, and study variances are both heterogeneous (Cochran's test for heterogeneity of study means, $X^2 = 22.26$, $P = 0.0045$, and Bartlett's test for heterogeneity of study variances, $X^2 = 21.47$, $P = 0.0060$, see Figure 6A). When Choi [49] was excluded (because of the very large CV), the cluster has improved somewhat, which would be expected as this study used different protocols (i.e. diffusion-weighted imaging). It can be seen from the data in Figure 6B that the study variances are no longer heterogeneous ($X^2 = 8.84$, $P = 0.2641$), although the study means remain heterogeneous ($X^2 = 19.54$, $P = 0.0066$). In contrast, meta-analysis of cluster 2 indicated that the study means are not heterogeneous ($X^2 = 4.77$, $P = 0.6874$), while the study variances are mildly heterogeneous ($X^2 = 15.54$, $P = 0.0206$, see Figure 7).

4. Discussion

The present systematic review and meta-analysis was performed to analyze the current studies on quantitative breast density using MRI and to determine the most appropriate technical/operational protocol. Through reviewing 38 studies from the literature, despite many methods and protocols available, no gold standard has been established with a wide range of heterogeneous methods or protocols used in these studies. To the best of our knowledge, this is the first comprehensive systematic review and meta-analysis of pooling the results of all breast density segmentation/measurement methods using MRI data. The analysis indicated that the non-contrast-enhanced T1-weighted acquisition was commonly utilized among all MR breast-imaging protocols. Another important finding of this analysis was that the FCM is the most frequently used algorithm amongst the breast density segmentation/measurement methods. Also, the results showed that a high level of heterogeneity was mainly associated with the breast-imaging protocols and the breast density segmentation/measurement methods.

Further attempts have been made by using clustering methods and meta-analysis to identify groups of studies which are as homogeneous as possible within groups and as heterogeneous as possible between groups. The included studies were grouped together into clusters based on their nearest neighbor Euclidean distances. On that basis, clusters 1 and 2 were considered as the most valuable results. Briefly, cluster 1 consisted of 9 studies [25–30,48,49,53], as shown from the data in Table 3 and Figure 6A that the CVs are varied in value, but in Choi [49] the CV is almost 100% because of the mean and SD are almost identical. This result may be explained by the fact that among the 8 studies [11,31,32,36–38,45,55], the breast-imaging protocol was a combination of contrast- and non-contrast-enhanced T1-weighted either with 2D spin echo or 3D gradient echo, while in Choi [49] the MRI protocol used was diffusion-weighted imaging. Consequently, it is advisable to exclude it from the meta-analysis to reduce the heterogeneity within cluster 1. Consistent with this hypothesis, the results have improved in somewhat, even though the study variances are not heterogeneous ($P > 0.05$), the study means are heterogeneous ($P < 0.05$) (Figure 6B). Although exclusion of Choi [49] did not reduce the heterogeneity, these results should be interpreted with caution. The discrepancy could be largely attributed to that although the MR breast-imaging protocols are not dissimilar (i.e., contrast- and non-contrast-enhanced T1-weighted), the breast segmentation/measurement methods are vice versa (i.e., FCM, FCM and N3, and in-house customized software). In contrast, cluster 2 included 8 studies, in 3 of these studies the breast density was reported as a (%DBV), while the remaining as a (%BD). Among these studies, the contrast- and non-contrast-enhanced T1-weighted was often used. From the data in Table 3 and Figure 7, it is apparent that the study means are not dissimilar ($P > 0.05$), although the study variances are heterogeneous ($P < 0.05$). Among the 21 studies included in the cluster analysis, although the fixed effect meta-analysis of cluster 2 has improved slightly, the heterogeneity within group still exist. There are two likely causes for this heterogeneity: the applied MR breast-imaging protocol and the used breast density segmentation/measurement methods.

Although the study has successfully confirmed the variation in the breast density segmentation/measurement methods using MRI data, the findings are subject to several limitations. First, the heterogeneity of study aims, the study design utilized, and the technical/operational methods applied, for instance, the MR breast-imaging protocol, MR scanner manufacturer, and the static magnetic field strength present challenges for performing the meta-analysis. Second, the breast density segmentation/measurement algorithm used is another limitation. Although we classified the included studies into discrete subgroups (i.e., FCM, FCM and N3, and interactive semi-automated threshold), and applied stratified analyses, the heterogeneity remains. Third, the definition of the breast density was inconsistent because some studies reported it as a percentage of dense breast volume, while the others as a percentage of breast density. Fourth, among the 38 studies included in this analysis, only 21 studies were eligible for meta-analysis due to the statistical requirements for the input values that should be in identical expression of measurement and dispersion. In addition, some of the included studies used the same set of the subject multiple times for different purpose and feature. Even though we decided to rectify the issue by selecting one of the results of data at random,

or by any meaningful clinical criterion, the heterogeneity continues to exist. Notwithstanding these limitations, the study further supports the idea of developing a standard MRI protocol for the quantitative assessment of breast density.

Future research can be suggested according to findings of this review. A recent study has reported the feasibility of creating a realistic 3D printed breast phantom for quality control purpose [58]. Thus, we consider 3D printing technique can be used to develop a patient-specific 3D printed breast phantom with different amounts of breast composition to quantify the volume of FGT. Further, the 3D printed model can be used to examine several MR breast-imaging protocols not only to measure the breast density but also to assess the impact of implementing various image quality parameters (i.e., FOV, matrix size and slice thickness) on the segmentation/measurement of breast density. Finally, the accuracy of different breast density/FGT segmentation methods can be determined.

5. Conclusion

This systematic review and meta-analysis confirms and substantiates the variation among the breast density segmentation/measurement methods using MRI. Furthermore, subgroup meta-analyses and further clustering methods indicated that a significant heterogeneity within and between groups exist. The analysis confirmed that the non-contrast-enhanced T1-weighted acquisition was commonly utilized among all MR breast-imaging protocols and the FCM is the most frequently used algorithm amongst the breast density segmentation/measurement methods. Future work will need to determine the most appropriate protocol and method for quantifying breast density using MRI.

Background: Despite increasing reports of 3D printing in medical applications, the use of 3D printing in breast imaging is limited, thus, personalized 3D-printed breast model could be a novel approach to overcome current limitations in utilizing breast magnetic resonance imaging (MRI) for quantitative assessment of breast density. The aim of this study is to develop a patient-specific 3D-printed breast phantom and to identify the most appropriate materials for simulating the MR imaging characteristics of fibroglandular and adipose tissues.

Methods: A patient-specific 3D-printed breast model was generated using 3D-printing techniques for the construction of the hollow skin and fibroglandular region shells. Then, the T1 relaxation times of the five selected materials (agarose gel, silicone rubber with/without fish oil, silicone oil, and peanut oil) were measured on a 3T MRI system to determine the appropriate ones to represent the MR imaging characteristics of fibroglandular and adipose tissues. Results were then compared to the reference values of T1 relaxation times of the corresponding tissues: $1,324.42 \pm 167.63$ and 449.27 ± 26.09 ms, respectively. Finally, the materials that matched the T1 relaxation times of the respective tissues were used to fill the 3D-printed hollow breast shells.

Results: The silicone and peanut oils were found to closely resemble the T1 relaxation times and imaging characteristics of these two tissues, which are $1,515.8 \pm 105.5$ and 405.4 ± 15.1 ms, respectively. The agarose gel with different concentrations, ranging from 0.5 to 2.5 wt%, was found to have the longest T1 relaxation times.

Conclusions: A patient-specific 3D-printed breast phantom was successfully designed and constructed using silicone and peanut oils to simulate the MR imaging characteristics of fibroglandular and adipose tissues. The phantom can be used to investigate different MR breast imaging protocols for the quantitative assessment of breast density.

Introduction

Breast magnetic resonance imaging (MRI) is a well-established approach in the diagnosis of breast disease, and it has become an important modality in the screening of

women at high-risk of breast cancer, preoperative staging of newly diagnosed breast cancer, and follow-up of breast cancer treatment (1-3). Hence, the European Society of Breast Imaging (EUSOBI) has recommended that breast

MRI be used as an adjuvant modality in women at high-risk of developing breast cancer (3), for those with (BRCA-positive genetic mutation carriers), family history, and/or high breast density (4).

Breast density, a measure of fibroglandular, dense tissue relative to fatty, non-dense tissue, is an independent risk factor of breast cancer (5-7). Consistent with this risk relationship, women who have dense breasts have a likelihood of developing breast cancer that is fourfold higher than those with fatty breasts (8,9). Currently various methods have been developed and introduced to segment/measure breast density using MRI: the utilization of a clustering algorithm, the segmentation of glandular and fatty tissues with an interactive thresholding algorithm, a logistic function approach and a curve-fitting algorithm; each has its advantages and limitations (10-14). However, there are certain drawbacks associated with the use of these algorithms as most of them are interpreted as measurements with a semi-automatic thresholding and segmentation methods. Likewise, different MR breast-imaging protocols have been used to differentiate between adipose and fibroglandular tissues ranging from non-contrast-enhanced T1-weighted to contrast-enhanced T1-weighted and diffusion-weighted acquisitions (15-19). Despite improvements in the quantitative assessment of breast density using MR imaging, there has been no general agreement about the optimal scanning protocol in this aspect. A recent systematic review and meta-analysis about the quantitative assessment of breast density has confirmed these variations among breast segmentation/measurement methods and MR breast-imaging protocols (20).

In recent years, there has been an increasing interest in 3D printing techniques, which are being used in different medical domains such as cardiovascular disease, orthopedic surgery, prosthetics, and neurosurgery (21-24). 3D-printed models have been shown to assist in the development of many surgical implants, which can improve the individual's understanding of such a complex anatomical structure (21). Several studies have produced anthropomorphic breast phantoms for X-ray imaging, but there is still insufficient data available for MR imaging (25-30). Carton *et al.* developed a 3D anthropomorphic breast phantom for the evaluation of image quality of 2D and 3D breast X-ray imaging systems. This phantom was based on a computational model and a rapid prototyping technique to generate breast phantom with different compositions, sizes, and shapes by using a tissue-equivalent material (25). While the phantom has effectively demonstrated a heterogeneous

distribution of the fibroglandular and adipose tissues that can be analogous to the clinical breast images, it has certain limitations in terms of its fabrication method and application. The phantom has been printed in slabs form, which is very complicated to manufacture and it is a time-consuming process (25).

Although some research has been carried out on the use of 3D printing techniques to develop a breast phantom for MR imaging, only few studies have attempted to generate a personalized 3D-printed breast phantom based on a realistic breast MR images that can be similar to the anatomical structures seen in human tissues (26-30). Burfeindt *et al.* (26) reported a new and convenient synthetic procedure to develop an MRI-derived 3D-printed breast phantom for the preclinical use in microwave breast-imaging experiments. Although the phantom has successfully simulated the dielectric properties of the biological breast tissues, it has been designed for microwave breast-imaging rather than for MR imaging system (26). Furthermore, the importance of realistic phantom structure in the assessment of photoacoustic breast imaging systems for the purpose of simulating the acoustic and optical breast tissues properties was demonstrated in a study by Dantuma *et al.* (27), in which a semi-anthropomorphic 3D-printed moulds derived from a MRI segmented numerical breast model was developed to produce real breast morphology using polyvinyl chloride plastisol (PVCP). However, there are limits to how far the phantom that has been designed for ultrasound and photoacoustic imaging can be used to simulate the MR imaging characteristics of breast tissues (27). Moreover, He *et al.* (28) developed a 3D-printed breast phantom for machine calibration and image optimization in multi-modalities imaging, where a mixture of PVC powder and softener (i.e., dioctyl terephthalate) was used as a tissue-mimicking material (TMM) of breast tissues. Although the study has successfully demonstrated the simulation of breast structures, it has certain limitations in terms of the lack of the appearance, variability, and heterogeneity of structures that are presented in the physiological tissues (28). Another potential limitation is that the T1 and T2 relaxation times of the materials were measured and found to be shorter than those reported in the physiological human breast tissues (28,29). While most of the aforementioned phantoms address their objectives in the medical imaging discipline, there are currently no phantoms available to evaluate the breast density based on a realistic morphology of breast structures derived from a MR images of human tissues. Likewise, uncertainties still exist about the most

Figure 1 Schematic flowchart demonstrates the process of developing a patient-specific 3D-printed breast model.

appropriate TMMs that can be used to simulate the MR-related characteristics and appearance of breast structures, particularly fibroglandular tissue. Such a personalized 3D-printed breast model could be used to examine different MR breast-imaging protocols not only to evaluate the breast density but also to determine the impact of applying various image quality parameters on the segmentation/measurement methods of breast density. Therefore, the aim of this study is to develop a patient-specific 3D-printed breast phantom and to identify the most appropriate materials for simulating the MR imaging characteristics of fibroglandular and adipose tissues.

Methods

Patient data

Ethical approval was obtained from Curtin University's Human Research Ethics Committee (HREC) and King Fahd Armed Forces Hospital's (Jeddah) Research and Ethics Committee. A random sample of patients with no history of breast disease was retrospectively reviewed from an existing breast MRI database. The criteria for selecting the subjects were the following: no previous surgery, no radiotherapy treatment on the chest wall, no history of breast cancer, and a Breast Imaging-Reporting and Data System (BI-RADS) classification of 1, indicating a negative likelihood of cancer. A 46-year-old woman was identified by a senior radiology resident to match the selection criteria. The breast MRI examination was performed using 1.5T system (MAGNETOM Aera, Siemens, Germany) with a dedicated breast coil (18 channels). The MR breast imaging protocol was chosen based on the recommendations of a recent systematic review and meta-analysis (20) as high-resolution non-contrast-enhanced T1-weighted images to allow a precise differentiation between adipose and fibroglandular

tissues: TR/TE 11.8/6.0 ms; matrix size 384×384; slice thickness 0.9 mm with no gap.

Image post-processing and segmentation process

A series of image post-processing and segmentation of the volumetric data was performed. First, the anonymized Digital Imaging and Communications in Medicine (DICOM) MR images were imported into the commercially available software Analyze 12.0 (AnalyzeDirect, Inc., Lexana, KS, USA) to segment the non-contrast-enhanced T1-weighted breast images. Second, the breast's boundary was delineated manually to distinguish the breast's body from the surrounding tissues (pectoral muscle, heart, lungs, and thorax) on each 2D slice based on grayscale intensity, displayed in a histogram. Then, the 3D breast volume was created by these 2D images and was subsequently used to design the 3D-printed breast model. Finally, the 3D segmented MR breast volume was saved as a standard tessellation language (STL) file for further image post-processing and 3D printing. *Figure 1* presents a schematic flowchart of the process of developing a patient-specific 3D-printed breast model using MRI data. For more details, the phantom consists of three main parts: the outer shell, simulating the skin layer, and the internal structures, which include fibroglandular and fat tissues, imitating the breast composition. To generate the skin shell, the STL file containing the 3D segmented MR breast volume was imported into the Blender software, version 2.79b (Blender Foundation, Amsterdam, Netherlands) to hollow the model and ensure that all the internal structures were perfectly extracted.

On the other hand, the DICOM MR breast dataset was loaded into the 3D Slicer software, version 4.10.2 [National Alliance for Medical Image Computing (NA-MIC)] to segment out the fibroglandular tissue and ensure that all

Figure 2 External structure of the patient-specific 3D-printed breast phantom that consists of 3 mm thick skin layer and compartments to be filled with fibroglandular and adipose tissues models.

the surrounding structures were completely removed. To increase reliability of the segmentation, each slice was segmented in different orientations using the threshold function, which was adjusted manually. This approach was used to threshold the DICOM dataset so that only the fibroglandular tissue structures were kept in the final segmented data. Subsequently, the segmented fibroglandular model was saved as a STL file and imported into the (version 3.5.474, Autodesk Inc., San Rafael, CA, USA) open-source software for further edit. Any deformities or free-floating objects were removed, and any holes were fixed during the editing process.

Overview and breast phantom design

This part is divided into three sections, each detailing the construction process related to the 3D-printed breast model components.

Skin layer

Based on the dimensions of a realistic tissue, the outer phantom shell had an average thickness of 3.0 mm, which corresponds to the normal skin thickness. The cover of the skin shell was designed using a computer-aided design (CAD) software. The skin shell and the cover were fabricated with fused deposition modelling (FDM) technology using polylactic acid (PLA) (Polymaker, Shanghai, China) on a Raise3D N2 Plus 3D printer (Raise3D, Irvine, CA, USA). The skin shell was printed with a layer height of 0.15 mm, average printing time of 40 hours, and a resolution of 12.5 μm (Figure 2).

Fibroglandular region

The fibroglandular models constitute the internal

component of the 3D-printed breast phantom. While various definitions of the term “breast density” have been proposed, in this study, the term “fibroglandular tissue” is used to refer to the breast density. Naturally, the fibroglandular region contains variable shapes and/or volumes of glandular tissue, includes fibrous or connective tissue. In clinical practice, the evaluation of fibroglandular tissue is based on a subjective assessment recommended by the American College of Radiology (ACR) BI-RADS, which is commonly used for mammography but also for MRI. The BI-RADS atlas can be described as a classification system that characterises breast density on the basis of the amount of fibroglandular tissue into four categories: (I) almost entirely fat, (II) scattered fibroglandular tissue, (III) heterogeneous fibroglandular tissue, and (IV) extreme fibroglandular tissue (31,32).

In order to simulate the MR imaging characteristics, the 3D fibroglandular models were designed as hollow structures with an average thickness of 2.0 mm. The fibroglandular models were fabricated using the digital light processing (DLP) technology on an Anycubic Photon S 3D DLP UV resin printer (Shenzhen Anycubic Technology Co. Ltd., Shenzhen, China) using white photopolymer resin (Magma H LINE Photopolymer Resin) from Magma Filament, Malaysia. A curing time of 10 sec per layer, a layer thickness of 0.05 mm, and a resolution of 47 μm were used to fabricate the fibroglandular models. The printing duration for both left and right fibroglandular models was about 17 hours (Figure 3).

Fat/adipose region

This region comprises a considerable part of the 3D-printed breast model. It consists of a selected material that simulates the MR imaging relaxation times of adipose tissue.

Figure 3 Fabrication of the hollow fibroglandular models using the Anycubic Photon S high-resolution 3D DLP UV resin printer. The thickness of the wall is 2.0 mm. DLP, digital light processing.

Fibroglandular TMMs

Agarose gels with different concentrations vary in their ability to simulate the MR imaging characteristics of T1 and T2 relaxation times of an extensive range of human tissues (33,34). In a study investigating the T1 and T2 relaxation times of four sample phantom liquids, Gach *et al.* (33) found that silicone oil had the longest T1 and T2 times on a 3T MRI system: $1,068.29 \pm 5.95$ and 566.40 ± 4.68 ms, respectively. These results provide further support to the hypothesis that agarose gel or silicone oil could be used to mimic the MR imaging characteristics of fibroglandular tissue based on T1 and/or T2 relaxation times. Thus, four different raw materials were scanned to determine which one could be used to mimic the T1 and/or T2 relaxation times of fibroglandular tissue. The candidate materials were silicone oil with a viscosity of $50 \text{ mm}^2/\text{s}$ at 25°C (TEX Chemical Inc., Country), agarose (Thermo Fisher, Waltham, MA, USA), silicone rubber RTV (Craftiviti Sdn. Bhd., Selangor, Malaysia), and fish oil (Blackmores, Sydney, Australia) (Figure 4).

Fat/adipose TMMs

As Niebuhr *et al.* (35) reported, olive oil successfully simulates the MR imaging relaxation times of adipose tissue in abdominal and pelvic tissues measured *in-vivo*. In another

study, Niebuhr *et al.* (34) found that peanut oil efficiently simulates the MR imaging characteristics of subcutaneous fat for pelvis phantoms. Peanut oil was preferred in this study for several reasons, including its relatively similar MR imaging characteristics (T1 and T2 relaxation times) for adipose tissue, its translucent appearance, and its high oxidation stability (34,35). These characteristics suggest that peanut oil could be a performed material to mimic the T1 and/or T2 relaxation times of breast adipose tissue. Two types of peanut oil were scanned for testing: peanut oil Basso (raw material: *Arachis hypogaea*; price: US\$ 5/1L; Basso), and peanut oil Pressed Purity (raw materials: oleic acid (96.2%) and linoleic acid (13.2%), price: US\$18/1.5L, Proteco Oils) (Figure 4).

Breast phantom construction

The T1 relaxation times of the five selected materials (agarose gel, silicone rubber with/without fish oil, silicone oil, and peanut oil) were measured at room temperature using a 3T MRI system to determine which ones could be used to mimic the MR imaging characteristics of fibroglandular and adipose tissues. The results were then compared to the reference values of T1 relaxation times of the corresponding tissues. Following this, the materials that matched the T1 relaxation times of the respective tissues were chosen to fill the 3D-printed hollow breast shells.

Figure 4 Test raw materials. (A) Silicone rubber; (B) silicone rubber with fish oil; (C) fresh silicone rubber; (D) silicone oil with a viscosity of $50 \text{ mm}^2/\text{s}$; (E) peanut oil (Basoo); (F) peanut oil (pressed purity); (G) agarose gel 0.5 wt%; (H) agarose gel 1.0 wt%; (I) agarose gel 1.5 wt%; (J) agarose gel 2.0 wt%; (K) agarose gel 2.5 wt%.

Results

3D-printed hollow models

The 3D-printed models of the hollow skin and fibroglandular region shells were scanned on a 3T MRI system (MAGNETOM Prisma, Siemens Healthcare, Erlangen, Germany) to check whether the models printed with the PLA or the photopolymer resin produce MR signals corresponding with these tissue features. Fortunately, no MR signal was observed from scanning the 3D-printed hollow models, indicating the possibility of using these materials for breast structure simulation and further patient models. It is important to note that the selected materials were checked when the 3D printing was initially performed and then checked again at the end of the breast phantom construction.

Sample characteristics

The five selected materials were scanned on the same 3T MRI system, with the materials placed in the 18-channel body and 32-channel spine coils. The MR breast scanning was chosen based on the institutional clinical protocol using

3D T1- and T2-weighted turbo spin echo (TSE) sequences: TR/TE 650.0/10.0 ms; matrix size 384×384 ; slice thickness 2.9 mm; no gap, and TR/TE 6,080.0/78.0 ms; matrix size 384×384 ; slice thickness 4.0 mm; no gap, respectively.

Figure 5 presents the MR imaging T1 relaxation times of the five materials (agarose gel, silicone rubber with/without fish oil, silicone oil, and peanut oil) simulating the breast composition. Figure 5D shows that the T1-weighted image of the silicone oil was associated with a mid-grey signal intensity, which is usually related to water-based tissues characterized by a moderate T1 relaxation time. On the other hand, Figure 5E,F shows that the T1-weighted images of the peanut oils indicated a high signal intensity, which was within expectation, as fat-based tissues have a short T1 relaxation time. In contrast, the T1-weighted images of the agarose gel with different concentrations, 0.5 to 2.5 wt%; were associated with low signal intensity, which is mainly observed in free water and other fluids (Figure 5G,H,I,J,K).

T1 relaxation times of the sample materials

The T1 relaxation times of these five materials are listed in Table 1. Silicone oil had a T1 relaxation time similar to

Figure 5 T1-weighted images. (A) Silicone rubber; (B) silicone rubber with fish oil; (C) fresh silicone rubber; (D) silicone oil with a viscosity of 50 mm²/s; (E) peanut oil (Basoo); (F) peanut oil (Pressed Purity); (G) agarose gel 0.5 wt%; (H) agarose gel 1.0 wt%; (I) agarose gel 1.5 wt%; (J) agarose gel 2.0 wt%; (K) agarose gel 2.5 wt%.

Table 1 T1 Relaxation times of different materials for tissue surrogates used in the experiment

Phantom, TMM	T1 (average SD, ms), 3T Siemens MR Scanner
Fibroglandular shell	No signal
Skin/outer shell	No signal
Silicone rubber	577.2±107.8
Silicone rubber with fish oil	902.1±120.5
Fresh silicone rubber	638.3±108.5
Silicone oil 50 mm ² /s*	1,515.8±105.5
Peanut oil (Basso)	405.4±15.1
Peanut oil (pressed purity)	404.1±10.5
Agarose gel 0.5 wt%	4015.5±100.2
Agarose gel 1.0 wt%	3,877.8±130.5
Agarose gel 1.5 wt%	3,404.8±255.9
Agarose gel 2.0 wt%	3,572.6±100.4
Agarose gel 2.5 wt%	3,617.2±101.5

*, Viscosity unit. TMM, tissue-mimicking material.

that of fibroglandular tissue: 1,515.8±105.5 ms. In contrast, the Basso and Pressed Purity peanut oils had T1 relaxation times analogous to that of adipose tissue: 405.4±15.1 and 404.1±10.5 ms, respectively. For comparison, the T1 and T2 relaxation times of fibroglandular and adipose tissues

measured using a 1.5T and a 3T MRI system are presented in *Table 2*.

As shown in *Table 1*, the agarose gel with different concentrations, ranging from 0.5 to 2.5 wt%, had the longest T1 relaxation times, which are similar to that of free water. The interesting finding is that the lowest concentration was associated with the highest T1 relaxation time. Overall, the results presented in *Table 1* and *Figure 5* indicate that the silicone and peanut oils closely resemble the MR imaging T1 relaxation times of the fibroglandular and adipose tissues, respectively. Therefore, these materials were chosen to fill the 3D-printed hollow models.

Figure 6 provides an overview of the construction process of the 3D-printed breast phantom. The two fibroglandular shell models were filled with a silicone oil and then sealed using UV-curable photopolymer resin. Following this, the filled fibroglandular shell models were fixed inside the skin shell model using acrylic-based adhesive. Further, the space between the fibroglandular and skin shell models was filled with peanut oil. A home-made silicone gasket and cover were used to enclose the breast phantom. Finally, the cover was tightened using the commercially available polycarbonate bolt and nuts.

Scanning of the 3D-printed breast phantom

The MR images of the phantom were acquired following the same breast imaging protocols described in the Results, Sample Characteristics. The phantom was scanned in a

Table 2 T1 and T2 Relaxation times of the breast tissues at 1.5T and 3T using FSE-IR scans (36)

Tissue (reference)	T1 (average SD, ms), 1.5T	T2 (average SD, ms), 1.5T	T1 (average SD, ms), 3T	T2 (average SD, ms), 3T
Adipose/fat	372.04±8.6	53.33±2.11	449.27±26.09	52.96±1.54
Fibroglandular	1,135.98±151.37	57.51±10.15	1,324.42±167.63	54.36±9.35

**Figure 6** Flow chart showing 3D construction of the breast phantom. 3D printing technique was used to create the hollow shells for skin and fibroglandular regions. Fibroglandular and adipose tissues were simulated using silicone and peanut oils, respectively.

prone position using a dedicated 18-channel breast coil. *Figure 7* shows the T1- and T2-weighted MR images of a patient-specific 3D-printed breast phantom using silicone and peanut oils as surrogates of the fibroglandular and adipose tissues, respectively. These oils presented an

acceptable level of contrast and MR-related characteristics in both the T1- and the T2-weighted images. One of the most noticeable features of this phantom is that it is slightly inhomogeneous. However, this feature simulates the considerable inhomogeneity as often observed among

Figure 7 MR images of the 3D printed breast phantom. (A) T1-weighted image; (B) T2-weighted image using TSE scans. TSE, turbo spin echo.

the irregular distribution of the patient. Overall, the results shown in *Table 1* and *Figure 5* indicate that the MR imaging T1 relaxation times of the silicone and peanut oils used for the simulation of fibroglandular and adipose tissues are similar to their respective reference values reported in the literature.

Discussion

This study aimed to develop a patient-specific 3D-printed breast phantom and to determine the most appropriate materials for simulating the MR imaging characteristics of fibroglandular and adipose tissues. Anthropomorphic shapes of skin and fibroglandular tissues were constructed using 3D-printing techniques based on the segmentations of breast MR images from a selected healthy patient's data. All the 3D skin and fibroglandular region shells were designed as hollow structures using PLA and photopolymer resin. Since no MR signal was generated by the 3D-printed hollow models of those corresponding shells, different materials were selected to search for suitable ones with silicone oil and peanut oil being the most appropriate materials with similar T1 relaxation times to fibroglandular

and adipose tissues.

It was assumed that the T1 relaxation times would effectively supplement and extend our knowledge about the selected materials since most organs' T1 values are five times longer than their T2 values. A comparison of the T1 relaxation times of the scanned materials with breast structure and literature reports showed that the silicone and peanut oils closely resemble the MR imaging T1 relaxation times of the fibroglandular and adipose tissues, respectively. Surprisingly, this study did not find a significant difference in the T1 relaxation times between different concentrations of agarose gel, which exhibited long T1 relaxation times, similar to that of water. Nevertheless, the agarose gel can be mixed with a gadolinium-based contrast agent for T1 adaptation, and can thus be used to simulate the MR imaging relaxation times of a wide range of human tissues. However, this would be costly and requires precautions when handling the contrast agent. Another unexpected finding was the slight difference in the T1 relaxation times between the Basso and Pressed Purity peanut oils. However, the observed difference was not significant. It is also worth noting that the Basso peanut oil was preferable due to its purity, availability, and low cost.

The most important clinically relevant finding was that the silicone and peanut oils demonstrated an acceptable level of contrast and MR-related characteristics of breast structures in both the T1- and the T2-weighted images. These findings are in line with Niebuhr *et al.* (34), who suggested that peanut oil efficiently simulates the MR imaging characteristics of subcutaneous fat for pelvis phantoms. In accordance with the present results, previous studies demonstrated that silicone oil with a viscosity of 50 mm²/s had the longest T1 and T2 relaxation times on a 3T MRI system (33,35). However, silicone oil was not previously used for simulating the MR-related characteristics of breast structures, particularly fibroglandular tissue. Thus, this study presents interesting findings to encourage more research along this direction in breast phantom.

The observed correlation between silicone oil's T1 relaxation time and fibroglandular tissue could be attributed to its chemical composition and physical properties such as viscosity and density. This preliminary finding; suggests that silicone and peanut oils can be used to efficiently simulate the MR imaging characteristics of breast structures and produce further models. An implication of this is the possibility to examine different MR breast imaging protocols to identify the most appropriate for the quantitative assessment of breast density. For future investigations, it might be possible to use different chemical compositions and physical properties of silicone oils to evaluate the MR imaging relaxation times of breast structures. Since the relationship between silicone oil and fibroglandular tissue has not been studied, further research is required to better understand it.

Although the study has successfully designed and constructed a patient-specific 3D-printed breast phantom, the findings are subject to several limitations. The study was not specifically designed to evaluate the mechanical properties of breast tissue components, such as elastic modulus or tissue strength. Examining the mechanical features along with the physical properties of selected materials could provide an idea of their characteristics and allow more detailed comparisons to the human breast tissue. Moreover, there are certain drawbacks to the use of 3D printing techniques for the construction of skin and fibroglandular hollow shells. One of them is the potential risk for some of the connected structures to break easily during the cleaning process. For this reason, several models of varying wall thicknesses, ranging between 1.0 and 2.5 mm, were printed. However, increasing the thickness of

photopolymer resin can cause considerable deformation of the fibroglandular structure. Another potential limitation is due to the complexity of the fibroglandular structure, with holes formed in the final mould. For this reason, a wrapping process was performed manually for each model to ensure that all the small gaps had been completely sealed.

A further study on a patient-specific 3D-printed breast phantom will be conducted with a focus on different percentages of fibroglandular tissue. This can correspond to the four categories of the ACR BI-RADS atlas, thus allowing an estimation of the volumes of fibroglandular tissue. Varying its proportions will allow the quantitative assessments of breast density to be performed.

Conclusions

In this study, a patient-specific 3D-printed breast phantom was successfully constructed using silicone and peanut oils to simulate the MR-related characteristics of breast fibroglandular and adipose tissues. The proposed methodologies can be used as a preliminary work for breast structure simulations and the construction of further patient models using MRI dataset. The phantom can be used to test different breast MR imaging protocols to determine the optimum scanning parameters and analysis algorithms for the quantitative assessment of breast density.

Acknowledgments

We like to thank King Fahd Armed Forces Hospital, Jeddah, Kingdom of Saudi Arabia, Mrs. Aghadeer Bana, Medical Physicist, and Ms. Khulud Al-Amoudi, Radiology Technologist/Patient Experience Western Regional Head for their cooperation in ethical approval and data collection. We deeply acknowledge the support of Dr. Sarah Bukhari, Senior Radiology Resident for her expertise guidance in gathering the required healthy patient's data.

Abstract: Despite the development and implementation of several MRI techniques for breast density assessments, there is no consensus on the optimal protocol in this regard. This study aimed to determine the most appropriate MRI protocols for the quantitative assessment of breast density using a personalized 3D-printed breast model. The breast model was developed using silicone and peanut oils to simulate the MRI related-characteristics of fibroglandular and adipose breast tissues, and then scanned on a 3T MRI system using non-fat-suppressed and fat-suppressed sequences. Breast volume, fibroglandular tissue volume, and percentage of breast density from these imaging sequences were objectively assessed using Analyze 14.0 software. Finally, the repeated-measures analysis of variance (ANOVA) was performed to examine the differences between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density with respect to the corresponding sequences. The volume of fibroglandular tissue and the percentage of breast density were significantly higher in the fat-suppressed sequences than in the non-fat-suppressed sequences ($p < 0.05$); however, the difference in breast volume was not statistically significant ($p = 0.529$). Further, a fat-suppressed T2-weighted with turbo inversion recovery magnitude (TIRM) imaging sequence was superior to the non-fat- and fat-suppressed T1- and T2-weighted sequences for the quantitative measurement of breast density due to its ability to represent the exact breast tissue compositions. This study shows that the fat-suppressed sequences tended to be more useful than the non-fat-suppressed sequences for the quantitative measurements of the volume of fibroglandular tissue and the percentage of breast density.

1. Introduction

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, has been determined as an independent risk factor for developing breast cancer [1–4]. Previous studies have reported that the potential risk of breast cancer in women with dense breasts is three- to five-fold higher than in women with fatty breasts [5–7]. Recent developments in breast cancer screening have intensified the need for a standardized imaging protocol and/or measurement method for the evaluation of breast density predominantly for women at an elevated risk of developing breast cancer, such as those with high breast density [4,8–10]. A considerable amount of literature has been published

on the assessment of breast density with several methods and algorithms proposed to segment and/or measure breast density using MRI datasets [11–19]. Nevertheless, research has consistently shown that these methods/algorithms seem to have certain drawbacks, mostly due to the use of a semi-automatic approach or a high-level of dependency on user interaction. Likewise, numerous MR breast-imaging protocols have been applied to the screening and/or the assessment of breast density, ranging from contrast- to non-contrast-enhanced imaging with or without the implementation of fat-suppression techniques [3,4,8–10,20–25]. To date, there has been little consensus on the optimal MR breast-imaging protocol and measurement method for breast density screening and/or assessment, especially in the context of women with dense breast tissues.

The dynamic contrast-enhanced (DCE)-MRI technique has been widely used for the screening of women at high risk of breast cancer and has been included in standard clinical breast MRI protocols [4,8]. Despite its long clinical success, DCE-MRI has certain disadvantages, such as long scanning time, high cost, and potential harm caused by the contrast agent [4,26]. Although contradictory findings have been reported in the literature about the precipitation and accumulation of gadolinium contrast-based agents in the brain, there is no general agreement regarding the risk of repeated gadolinium administration [4,27–29]. Nevertheless, questions have been raised about the safety of prolonged use of DCE-MRI as a primary screening method for the detection of breast cancer and/or the assessment of breast density. On the other hand, the fat-suppression technique has been suggested in breast MRI to improve the visibility of pathology, contrast enhancement, and image quality, thus allowing for better differentiation between dense fibroglandular and non-dense fatty tissues [17,30]. It has been combined with other techniques and/or sequence types due to the difficulty of eliminating the high signal intensity associated with fatty tissues [17,30]. Several methods have been proposed for fat suppression in breast MRI, including chemical shift spectral-selective saturation (CHESS) based on the chemical shift variation between fat and water, inversion recovery (IR) based on variation in T1 relaxation time, hybrid CHESS–inversion recovery methods, and Dixon fat–water separation based on phase variation between fat and water signals at different echo times (TEs) [3,17,20,30–32].

Non-fat-suppressed and fat-suppressed T1-weighted images are frequently used with either 2D spin echo (SE) or 3D gradient echo (GRE) in standard clinical breast MRI protocols [8,17]. Nevertheless, there is no consensus as to which of these sequences/techniques is the most efficient in this regard. The American College of Radiology (ACR) has recommended that the fat-suppressed images with high spatial resolution be used in clinical breast MRI protocols as images acquired with this sequence can eliminate misregistration, which mainly occurs when a patient moves during the acquisition of pre- and post-contrast images [8,17]. However, this recommendation contrasts with that of the European Society of Breast Imaging (EUSOBI), which considers non-fat-suppressed sequences based on the acquisition of subtraction images more useful [17,33]. Despite this, there seems to be some consensus that other breast MRI techniques, including T2-weighted images, DCE, and diffusion-weighted imaging (DWI), tend to benefit from its combination with fat-suppression techniques for several reasons [1,8,17,30]. For instance, turbo inversion recovery magnitude (TIRM), a type of inversion recovery sequence with the advantage of short image acquisition time, has been widely used in the delineation of tumor and/or lymphatic spread and could possibly be combined with fat-suppression technique for the assessment of breast density [4,34]. Patient-specific 3D-printed breast models, derived from a patient's MR imaging data and comparable to the anatomical structures of human tissues, can be a valuable tool for examining different breast MRI protocols, testing the radio frequency coils, and evaluating system performance [35–42]. The aim of this study is to determine the most appropriate MR breast-imaging protocols for the quantitative assessment of breast density using a personalized 3D-printed breast model based on an objective comparison between the non-fat-suppressed and fat-suppressed sequences. We hypothesize that fat-suppressed sequences allow for more accurate assessment of breast density while TIRM with fat-suppressed sequence further enhances its accuracy in quantitative assessment of breast density.

2. Materials and Methods

2.1. Study Subject: A Personalized 3D-Printed Breast Model

A personalized 3D-printed breast model which was developed in our previous study [43] used 3D-printing techniques and tissue-mimicking materials (TMMs) with the intention of simulating the MR-related characteristics of fibroglandular and adipose breast tissues for the quantitative assessment of breast density. The model consisted of two main parts: an outer shell to simulate the breast outline, and an inner shell filled with silicone and peanut oils to mimic the internal breast compositions. The results showed that the silicone and peanut oils successfully resemble the MR-imaging characteristics and T1 relaxation times of fibroglandular and adipose breast tissues, respectively [43]. This combination of findings further supports the hypothesis that such a model could be used to examine different MR breast-imaging protocols in order to determine the optimum for the quantitative assessment of breast density. Figure 1 demonstrates the schematic flowchart of the construction process for developing a personalized 3D-printed breast model.

Figure 1. Flow chart demonstrates the construction process of the personalized 3D-printed breast model for MRI. Reprinted with permission under open access from Sindi et al. [43].

2.2. MR Scanning Protocol

The 3D-printed breast model was scanned on a 3T MRI system (MAGNETOM Prisma, Siemens Healthcare, Erlangen, Germany) in a prone position using a dedicated 18-channel breast coil. Different MR imaging sequences were applied to improve the visibility of structure and contrast enhancement, thus allowing for better differentiation between fatty non-glandular and glandular structures. Table 1 displays the image acquisition parameters of the six MR imaging sequences used in this study.

2.3. Quantitative Measurement: Breast Volume, Fibroglandular Tissue Volume, and Percentage of Breast Density

Breast volume and fibroglandular tissue volume were objectively measured with a semi-automated segmentation method using a commercially available biomedical imaging software, Analyze V 14.0 (AnalyzeDirect, Inc., Lexana, KS, USA). Two steps were performed to measure the percentage of breast density from MRI data: breast segmentation and fibroglandular tissue segmentation. The purpose of breast segmentation is to separate the breast's body from the surrounding structure and/or background, while fibroglandular tissue segmentation separates the glandular from the fatty tissue.

To differentiate the breast's body from the background, the breast's boundary was first delineated semi-automatically using an interactive tool based on the threshold signal intensity function by setting seed points on a series of 2D axial slices comprising the entire breast volume. The minimum and maximum threshold limits were then adjusted to define the region of interest. The software spontaneously interpolated between these slices and generated a mask of the whole breast volume. Once the breast's body was segmented out, an automated method incorporating several morphological processing operations and spatial filters were used to segment out the fibroglandular tissue from the surrounding fatty tissue. Upon completion of this segmentation process, the breast volume and fibroglandular tissue volume were measured using a 3D-measurement tool based on the size intensity function. The percentage of breast density was then computed as the ratio of the fibroglandular tissue volume relative to the total breast volume. Finally, the results were analyzed to assess the differences between the measurement of breast volume, fibroglandular tissue volume, and percentage of breast density based on the different MRI sequences.

2.4. Data Synthesis

The acquisition of the different MRI sequences and the implementation of several fat-suppression techniques, as applied in the proposed study, are considered to be technically heterogeneous. To address this complexity and provide more objective comparisons, the six MRI sequence compartments were re-configured into a two-way cross-classification, namely two fat-suppression categories: non-fat-suppression MRI sequences (i.e., MR Seq. 1, 2, and 3) and fat-suppression MRI sequences (i.e., MR Seq. 4, 5, and 6). For the purpose of the analysis, the segmentation processes of both the breast volume and the fibroglandular tissue volume were performed three times, thus extracting three segments from each MRI sequence. Subsequently, the measurements were conducted three times with respect to the volume of the breast, the volume of the fibroglandular tissue, and, thereby, the percentage of the breast density.

Table 1. Image acquisition parameters of the MR breast-imaging sequences using a personalized 3D-printed breast model.

No.	MRI Sequence	Acquisition Type	Orientation, Slice No.	TR (ms)	TE (ms)	TI (ms)	FOV (mm)	Matrix Size	Slice Thickness (mm)	Flip Angle (°)	NSA	Scan Time (min)
1.	Non-fat-suppressed TSE (T2W)	2D	Axial, 33	6080	78		350 × 350	336 × 448	4.0	80	1	1.10
2.	Non-fat-suppressed TSE (T1W)	2D	Axial, 37	709	10		350 × 350	224 × 320	2.9	130	2	2.38
3.	Non-fat-suppressed TSE SPACE (T1W)	3D	Axial, 88	600	3.4		400 × 400	256 × 256	1.6	120	2	2.47
4.	Fat-suppressed TSE SPACE (T1W)	3D	Axial, 88	1500	3.4		400 × 400	256 × 256	1.6	120	1	4.58
5.	Fat-suppressed TSE SPACE SPAIR (T1W)	3D	Axial, 88	1500	3.4		400 × 400	256 × 256	1.6	120	1	4.58
6.	Fat-suppressed IR/PFP TIRM (T2W)	2D	Axial, 37	4120	70	230	340 × 340	358 × 448	3.0	80	2	1.51

Abbreviations—TR: repetition time; TE: echo time; TI: inversion time; FOV: field-of-view; NSA: number of signal averages/excitations; 2D: two-dimensional; 3D: three-dimensional; TSE: turbo (fast) spin-echo; T1W: T1-weighted; T2W: T2-weighted; SPACE: sampling perfection with application optimized contrasts using different flip angle evolution; SPAIR: spectral attenuation inversion recovery; IR: inversion recovery; PFP: partial Fourier phase; TIRM: turbo inversion recovery magnitude.

2.5. Statistical Analysis

Statistical analyses were conducted using NCSS V 19.0.5 (NCSS, LLC., Kaysville, UT, USA). The repeated-measures analysis of variance (ANOVA) was performed to examine the difference between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density with regard to the non-fat-suppressed and fat-suppressed MRI sequences. This variance model was employed to account for the variation both between sequences (i.e., between subjects) and within repeated measurements (i.e., within subjects). Significance levels were set at the 5% level. Descriptive data and box plots were also produced for all variables, demonstrating the distribution and median of breast volume, fibroglandular tissue volume, and percentage of breast density measured in the non-fat-suppressed and fat-suppressed imaging groups.

3. Results

3.1. Scanning of the Personalized 3D-Printed Breast Model

Figure 2 shows the MR images of the personalized 3D-printed breast model using silicone and peanut oils as surrogates for fibroglandular and fatty breast tissues, respectively, for the various scanning sequences. These oils produced a reasonable level of contrast and MR-related characteristics amongst the T1- and T2-weighted images with and without the implementation of the fat-suppression techniques. Although the most noticeable feature of the personalized 3D-printed breast model was that it was somewhat inhomogeneous, this feature nevertheless mimics the substantial inhomogeneity sometimes encountered in patients' irregular distributions.

The suppression of fat signals in the T1-weighted images with both SPACE and SPAIR acquisitions did not substantially increase the contrast enhancement or visualization between the dense fibroglandular and non-dense fatty structures (Figure 2D,E). A possible explanation for this could be that these types of acquisitions are highly affected by inhomogeneity in the magnetic field, demonstrating inhomogeneous fat suppression in the fatty structures. On the contrary, Figure 2F shows that the fat-suppressed T2-weighted image with TIRM acquisition demonstrated a homogenous high signal intensity in the fibroglandular structure and a low signal intensity in the fatty structure for both the right and left breasts. The suppression of fat signals significantly improved the contrast between the fibroglandular and fatty structures, further enhanced visualization, and provided more anatomical information which may assist in the segmentation and/or quantification of breast density.

Figure 2. Cont.

(A) Non-fat-suppressed TSE (T2W); (B) Non-fat-suppressed TSE (T1W); (C) Non-fat-suppressed TSE SPACE (T1W); (D) Fat-suppressed TSE SPACE (T1W); (E) Fat-suppressed TSE SPACE SPAIR (T1W); (F) Fat-suppressed IR/PPF TIRM (T2W). For pulse sequences, refer to Table 1.

3.2. Quantitative Measurement of Breast Volume, Fibroglandular Tissue Volume, and Percentage of Breast Density

Table 2 displays the quantitative measurements (mean and standard deviations) of the breast volume, fibroglandular tissue volume, and percentage of breast density for the different MRI sequences. For the SPACE T1-weighted images (i.e., MR Seq. 3 and 4), there was evidence of a difference in breast density between the non-fat-suppressed sequence ($7.719 \pm 0.366\%$) and the fat-suppressed sequence ($11.698 \pm 0.351\%$). This difference can be explained by the direct relationship between fibroglandular tissue volume and breast density, as shown in Table 2, the volume of fibroglandular tissue measured in the fat-suppressed sequence (i.e., MR Seq. 4) was higher than that in the non-fat-suppressed sequence (i.e., MR Seq. 3): $53.940 \pm 1.083 \text{ cm}^3$ and $34.261 \pm 1.809 \text{ cm}^3$, respectively.

For the breast density assessment, there was a substantial difference between the non-fat-suppressed sequence ($5.401 \pm 0.165\%$) and the fat-suppressed sequence ($9.498 \pm 0.930\%$) measured in the T2-weighted images, MR Seq. 1 and MR Seq. 6, respectively. This difference might explain the relatively good improvement in the contrast between the fibroglandular and fatty structures (Figure 2F) owing to the implementation of the fat-suppression technique, which had a major effect on the segmentation process and, therefore, the measurement of breast density.

By contrast, the means of the breast density for the non-fat suppressed (i.e., MR Seq. 2) and the fat-suppressed (i.e., MR Seq. 5) were $7.733 \pm 0.365\%$ and $10.467 \pm 0.084\%$, respectively. A comparison of MR Seq. 2 and MR Seq. 5 revealed that the breast volume, fibroglandular tissue volume, and percentage of breast density measured in the fat-suppressed sequence tended to be higher than that measured in the non-fat-suppressed sequence (Table 2).

Table 2. Results of the estimated mean and standard deviation of breast volume, fibroglandular tissue volume, and percentage of breast density for the different MRI sequences using a personalized 3D-printed breast model.

MRI Sequence *	Breast Volume (cm ³)		Fibroglandular Tissue Volume (cm ³)		Breast Density (%)	
	Mean	SD	Mean	SD	Mean	SD
Non-fat-suppression group (MR Sequences 1, 2, and 3)						
MR Seq. 1 (N = 3)	592.291	5.065	31.984	0.735	5.401	0.165
MR Seq. 2 (N = 3)	388.793	4.159	30.067	1.159	7.733	0.365
MR Seq. 3 (N = 3)	443.884	11.913	34.261	1.809	7.719	0.366
Combined (N = 9)	474.989	91.406	32.104	2.144	6.952	1.194
Fat-suppression group (MR Sequences 4, 5, and 6)						
MR Seq. 4 (N = 3)	461.188	4.699	53.940	1.083	11.698	0.351
MR Seq. 5 (N = 3)	462.948	11.882	48.456	1.140	10.467	0.084
MR Seq. 6 (N = 3)	715.784	32.097	67.794	3.623	9.498	0.930
Combined (N = 9)	546.640	128.031	56.730	8.854	10.555	1.077

* For pulse sequences, refer to Table 1.

3.3. Comparison of Measurements Between Non-Fat-Suppression and Fat-Suppression Groups

Table 3 demonstrates the results (mean, standard error, F-ratio, and P-value) of the repeated-measures ANOVA of breast volume, fibroglandular tissue volume, and percentage of breast density with respect to the non-fat-suppression and fat-suppression groups. The box plots of these parameters for the two groups are shown in Figure 3.

Table 3. Results of the repeated-measures ANOVA, including total mean, standard error (SE), F-ratio, probability level (Prob level) of breast volume, fibroglandular tissue volume, and percentage of breast density between two imaging groups: non-fat-suppressed and fat-suppressed MRI pulse sequences.

Breast Density Parameter	Non-Fat-Suppressed (N = 9)		Fat-Suppressed (N = 9)		F-Ratio	Prob Level **
	Mean	SE (4 df *)	Mean	SE (4 df *)		
Breast volume (cm ³)	474.989	73.639	546.640	73.639	0.47	0.5293
Fibroglandular tissue volume (cm ³)	32.104	4.158	56.730	4.158	17.54	0.0138
Breast density (%)	6.952	0.709	10.555	0.709	12.90	0.0229

* The degrees of freedom; ** The significance level of the F-ratio (the probability that the difference between data is significant or not). The significant difference between the quantitative measurements of breast volume, fibroglandular volume, and percentage of breast density based on the non-fat suppressed and the fat-suppressed MRI sequences was determined at the 5% level.

For breast volume, although the mean measured from the non-fat-suppression group (474.989 cm³) tended to be lower than that from the fat-suppression group (546.640 cm³), the difference was not statistically significant ($p = 0.5293$), with an F-ratio of 0.47 and a standard error for both means of 73.639. However, for the fibroglandular tissue volume and the percentage of breast density, the repeated-measures ANOVA showed that the difference between the non-fat-suppression group and the fat-suppression group was statistically significant at the 5% level. The values measured from the non-fat-suppression group were lower than those from the fat-suppression group, as shown in Table 2; Table 3. The mean volume of fibroglandular tissue was 32.104 cm³ for the non-fat-suppression group and 56.730 cm³ for the fat-suppression group, which was statistically significant ($F = 17.54$; $p = 0.0138$), with a standard error of 4.158. Likewise, there was a significant difference ($F = 12.90$; $p = 0.0229$) between the two groups: the mean breast density measured in the non-fat-suppression

group (6.952%) tended to be lower than that of the fat-suppression group (10.555%), with a standard error for both means of 0.709.

Figure 3. Cont.

Figure 3. Box plots demonstrate the distribution and median of three main parameters: (A) breast volume, (B) fibroglandular tissue volume, and (C) percentage of breast density measured on the non-fat-suppressed and the fat-suppressed MRI sequences. The six MRI sequences compartments were re-configured into a two-way cross-classification, namely two fat-suppression categories. As shown, “1/No” is the non-fat-suppression, “2/Yes” is the fat-suppression, which are on the *x*-axis, while the three parameters measured with respect to these two corresponding categories are on the *y*-axis.

4. Discussion

Recently, for women with an elevated risk of developing breast cancer, such as those with high breast density, the importance of establishing a standardized MRI protocol and/or measurement method for the assessment of breast density has increased in clinical and research domains. Although fat-suppressed and non-fat-suppressed sequences have frequently been included for both T1- and T2-weighted images in clinical breast MRI protocol, there is no agreement on which of these sequences should be used in this regard [1,8,17,30]. The current study was designed to determine the most appropriate MRI sequence for the quantitative assessment of breast density using a personalized 3D-printed breast model [43] based on an objective comparison between fat-suppressed and non-fat-suppressed sequences. Six MRI sequences were acquired and categorized into fat-suppression and non-fat-suppression categories to examine the difference between the quantitative measurements of breast volume, fibroglandular tissue volume, and percentage of breast density between these two imaging groups.

Comparing the two fat-suppression groups, the repeated-measures ANOVA showed that the differences between the non-fat-suppressed and fat-suppressed MRI sequences (i.e., MR Seq. 1, 2, and 3 and MR Seq. 4, 5, and 6) were statistically significant at the 5% level for both fibroglandular tissue volume and percentage of breast density. On the contrary, the observed difference between these corresponding sequences was not statistically significant with respect to breast volume. The current findings seem to be consistent with other research documenting that the assessment of breast density is considered

to fluctuate with MRI sequences and with the application of fat-suppression techniques [3,16,17]. A comparison of our results with Chang et al. [17], who suggested that breast volumes measured in T1-weighted sequences with and without fat suppression were almost identical for a similar case, is encouraging. Although their results differed from the current study, given that the breast density parameters were analyzed only on the T1-weighted sequences, they are still consistent with our findings, which showed that there was no evidence of a difference in the breast volumes between the non-fat-suppression and the fat-suppression groups (Table 3). A possible explanation for this could be that the measurement of breast volumes based on these two groups was not considerably influenced by the applied imaging techniques and/or segmentation method. Despite the breast volumes measured from the T2-weighted sequences with and without fat suppression being higher than those of the T1-weighted sequences, the difference between the two imaging groups was not significant. This can be attributed to the matrix sizes of the T2-weighted images used with the non-fat-suppressed and fat-suppressed sequences (i.e., MR Seq. 1 and 6), which were 336×448 and 358×448 , respectively.

However, there was a statistically significant difference between fibroglandular tissue volume and percentage of breast density, indicating higher values in the fat-suppressed sequences (MR Seq. 4, 5, and 6) compared to the non-fat-suppressed sequences (MR Seq. 1, 2, and 3), as shown in Tables 2 and 3. This difference can be explained in part by the relatively good contrast enhancement and/or visualization observed between the fibroglandular and the fatty structures resulting from the suppression of fat signals, as was evident in the TIRM with fat-suppressed T2-weighted image (Figure 2F). Although the signal-to-noise ratio and tissue contrast in the non-fat-suppressed images were higher than those in the fat-suppressed images, the results for the fat-suppression group were significantly higher than those for the non-fat-suppression group. Nevertheless, the scanning times for the fat-suppressed sequences were longer than those for the non-fat-suppressed sequences, except for the TIRM, which was 1 min 51 s. As shown in Table 2, breast volume, fibroglandular tissue volume, and percentage of breast density analyzed with TIRM were considerably higher than those of the T1- and T2-weighted sequences with and without fat suppression. Compared to these sequences, the observed increase in breast density parameters from the T2-weighted and TIRM acquisition was probably due to their individual characteristics: the T2-weighted image with fat-suppression technique is known to improve fluid intensity visualization, while TIRM is known to provide more anatomical information [4,44]. Similar findings were obtained by Bu et al. [4], who suggested that the combined DWI and TIRM could be used as an alternative imaging protocol for the screening of women with dense breast tissue. Despite being preliminary findings, our study indicates that TIRM could be incorporated with fat-suppression techniques for the assessment of breast density. Therefore, the fat-suppressed T2-weighted image with TIRM acquisition can be a promising technique for the quantitative assessment of breast density, although further research should be conducted to verify this suggestion.

Overall, the observed differences in breast density measurements between the fat-suppression and non-fat-suppression groups can be attributed to several factors: the segmentation method, image quality, scanning/technical parameters, and tissue contrast achieved by using different MRI pulse sequences. There are, however, other possible reasons; the applied fat-suppression techniques are more susceptible to magnetic field inhomogeneity, especially in the case of the 3T MRI system, where the field heterogeneity can be more protuberant. As shown in Figure 2, the high levels of inhomogeneity in both the fat-suppressed and non-fat-suppressed images might be the major factor—if not the only factor—that can cause such a variation in the segmentation and/or quantification of breast density parameters.

Although this study suggests that the fat-suppressed sequences are more useful than the non-fat-suppressed sequences for the segmentation/measurement of fibroglandular tissue volume and breast density, it is subject to several limitations. First, the assessment of breast density parameters was carried out on a developed 3D-printed breast model using silicone and peanut oils as tissue-equivalent materials and may not reflect the exact distribution of both fibroglandular and fatty structures as seen in human breast tissues. This limitation could be addressed by further research with the use of

more realistic breast models for MRI scanning. Second, the high levels of inhomogeneity in both the fat-suppressed and non-fat-suppressed images could have influenced the segmentation and breast density measurements. This is unavoidable due to the complexity of the MRI scanning sequences. Third, the breast density parameters were segmented and measured using a semi-automated method, which implies that the prospective source of variation between such measurements could be due to a high level of dependency on user interaction. For this reason, multiple segmentations/measurements of the breast density parameters were consistently conducted by the same observer to minimize potential intra-observer variations. However, the applicability of the proposed segmentation and measurement method is relatively high as an interactive 3D tool and would be more useful in the long-term assessment of breast density. Finally, with the implementation of different imaging techniques, acquisition types, and fat-suppression methods, caution must be applied as the findings might not be transferable to clinical practice without further investigation.

For future research, a greater focus on the TIRM with a fat-suppression technique could produce interesting findings on the quantification of breast density, especially for women at high risk of developing breast cancer. Quantitative assessment of breast density parameters in participants' clinical breast MRI datasets, could also be used to investigate and validate this observation.

5. Conclusions

A significant difference was found between the non-fat-suppression and fat-suppression MRI sequences for the quantitative measurements of the volume of fibroglandular tissue and the percentage of breast density. In general, the findings suggest that fat-suppressed sequences are an efficient scanning technique that reflects the exact composition of breast tissues. TIRM with fat-suppressed T2-weighted sequence can be a promising imaging protocol for the segmentation and/or quantification of breast density. Further research is required to verify these findings so that the optimal breast MRI protocols can be developed for clinical application.

ABSTRACT

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, has been confirmed as an independent risk factor of breast cancer. Although some research has been carried out on the quantitative assessment of breast density using breast MRI, there has been no report about the optimal MRI approach in this regard. This editorial highlights key findings reported by a recently published systematic review and met-analysis through analysing the current methods for quantifying breast density using MRI. Cluster analysis was applied to identify the statistical similarities within and between groups based on a Nearest Neighbour/Single Linkage. The analysis found that the non-contrast-enhanced T1-weighted acquisition is one of the most common MR breast-imaging protocols. Also, the fuzzy c-means clustering is the most widespread used algorithm among all breast density segmentation/measurement methods.

Key Words

Breast density, fibroglandular-tissue, magnetic resonance imaging, non-contrast-enhanced T1-weighted, segmentation, fuzzy c-mean clustering

Implications for Practice:

1. What is known about this subject?

Magnetic resonance imaging (MRI) provides excellent details of soft tissue contrast that can be used reliably to differentiate between fibroglandular and fatty tissues through detection of slight changes in density. However, there has been little agreement on what the optimal approach to assess breast density using MRI.

2. What new information is offered in this editorial?

Use of non-contrast-enhanced T1-weighted acquisition and fuzzy c-means clustering algorithm can allow for accurate assessment of breast density. This editorial analyses the current literature by demonstrating the usefulness of using non-contrast-enhanced T1-weighted images and fuzzy c-means clustering algorithm for the quantitative assessment of breast density.

3. What are the implications for research, policy, or practice?

3D printing techniques can be used to design a patient-specific 3D printed breast phantom to develop the optimal MR breast-imaging protocols. An important implication of this is the possibility of quantifying the amount of fibroglandular-tissue, thus simulating the risk factor of breast cancer.

Introduction

Breast density, a measure of dense fibroglandular tissue relative to non-dense fatty tissue, is an independent risk factor for breast cancer.¹⁻³ This finding confirms the association between breast density and breast cancer as women with dense breasts their likelihood of developing breast cancer is greater than those with fatty breasts.^{4,5} Clinically, the assessment of breast density is performed qualitatively using the American College of Radiology (ACR) Breast Imaging-Reporting and Data System (BI-RADS) atlas, according to which density has different classification based on the amount of fibroglandular

tissue.⁶ The main limitation of the BI-RADS atlas, however, is the inter- and intra-reader variability, as a result many methods are proposed in the literature regarding the quantification of breast density using MRI data.^{7,8} Most of these methods are interpreted as measurements with a semi-automatic thresholding and segmentation approach, to date (and to the best of our knowledge), no consensus has been reached about the optimal approach to quantify breast density. This has been confirmed by our recent systematic review and meta-analysis on the quantitative assessment of breast density using MRI.⁹ This editorial attempts to summarize some key findings from the current methods used for the quantitative assessment of breast density using MRI and highlight future research directions.

Quantitative assessment of breast density based on MRI protocols and segmentation/measurement methods

The methodological approach taken in this review is a mixed methodology based on “*metamean*” function in the R system, Version 3.4.1 (<http://www.r-project.org/>) and cluster analysis using the SPSS Statistics software V 25.0. A total of 38 studies were eventually included in the systematic review and meta-analysis.^{1-3,5, 9} A wide range of MR breast-imaging protocols were identified to differentiate between fibroglandular and adipose tissues, with the non-contrast-enhanced T1-weighted either with 2D spin echo or 3D gradient echo being one of the protocols most often used. Regarding breast density segmentation/measurement methods of the studies, 20 studies (51.28%) used FCM clustering algorithm, 7 studies (17.95%) FCM and N3 algorithm, 4 studies (10.26%) in-house software, and one study (2.56%) manual software, whilst two studies did not mention this information. However, because of the heterogeneity nature of the study, the included studies were categorized into different clusters based on their statistical similarities using Euclidean distance and nearest neighbour agglomeration method. Eligibility criteria required individual studies to have independent study sample size, mean, and standard deviation. As a result, only 20 studies fulfilled the inclusion criteria of clustering analysis (Figure 1).⁹

A comparison of the two forest plots of cluster 1 (consisted of 9 studies) and 2 (consisted of 8 studies) reveals that the study means (i.e., cluster 1) are heterogeneous ($X^2 = 19.54$, $P = 0.0066$), however, the study variances are not heterogeneous ($X^2 = 8.84$, $P = 0.2641$), as shown in Figure 2. On the other hand, the study means (i.e., cluster2) are not heterogeneous ($X^2 = 4.77$, $P = 0.6874$), whereas the study variances are mildly heterogeneous ($X^2 = 15.54$, $P = 0.0206$) as indicated in Figure 3. Overall, there are two likely causes for the heterogeneity within the breast density studies: the used MR breast-imaging

protocol and the applied breast density segmentation/measurement method. The evidence presented thus far supports the idea that optimal approach for the assessment of breast density should be established.

Summary and conclusion

The editorial further confirmed the high level of variation within the breast density studies, a possible explanation for these results may be due to the lack of adequate MR breast-imaging protocols and ideal breast density segmentation or measurement methods. A reasonable approach to tackle this issue could be to develop a patient-specific 3D printed breast phantom with different amounts of breast composition to quantify the volume of fibroglandular-tissue. Further, the 3D printed model can be used to develop optimal MR breast-imaging protocols, therefore, simulating the risk factor of developing breast cancer. 3D printing has been increasingly used in different medical fields ranging from orthopaedic surgery to cardiovascular disease and pre-surgical assessment of tumours.¹⁰⁻¹³ Use of 3D printing in breast tissue is limited¹⁴, thus, personalized 3D printed breast models could be a novel approach to overcome current limitations in utilising breast MRI for quantitative assessment of breast density.

ABSTRACT

Three-dimensional (3D) printing has become an increasingly developed technique in the medical field and has been used in many clinical applications. Research has consistently shown that 3D-printed models derived from patient's imaging data can serve as valuable tools for examining different breast-MRI protocols, testing radiofrequency coils, and evaluating system performance. This editorial highlights the utility of personalized 3D-printed breast model for the quantitative breast density assessment using MRI. A personalized 3D-printed breast model was developed and fabricated using silicone and peanut oils to mimic the MR-associated properties of fibroglandular and adipose breast tissues. The silicone and peanut oils' T1 relaxation times were correspondingly determined on a 3T MRI system and linked to the tissue reference values.

Key Words

Magnetic resonance imaging (MRI), breast density, fibroglandular-tissue, three-dimensional printing, model, silicone oil, peanut oil, quantitative, assessment

Implications for Practice:

1. What is known about this subject?

Magnetic resonance imaging (MRI) is widely used as an adjuvant modality for the screening of women at high-risk of developing breast cancer, such as those with high breast density.^{1,2} Although some research has been conducted on the use of 3D printing techniques to develop breast phantoms for MRI, there are currently no phantoms available for quantitative breast density assessment based on a realistic morphology of breast structures derived from MR images of human tissues.³⁻¹⁰

2. What new information is offered in this editorial?

Personalized 3D-printed breast model using silicone and peanut oils simulates the MR-related characteristics and appearance of fibroglandular and adipose breast tissues, respectively. This editorial summarises our research experience of using 3D printing techniques and tissue mimicking materials (TMMs) to resemble the T1 relaxation times of the corresponding breast tissues.

3. What are the implications for research, policy, or practice?

A personalized 3D-printed breast model can be used to identify the optimal breast MRI protocol and measurement method for the quantitative assessment of breast density, thus estimating the risk of developing of breast cancer.

Introduction

Breast density-an autonomous risk element of breast cancer-is defined as a measure of dense fibroglandular tissue relative to non-dense fatty tissue.¹¹⁻¹³ In line with this risk association, women with dense breasts have shown a greater probability of inducing breast cancer relative to those with fatty breasts.^{14,15} Although some research has been carried out on the development of anthropomorphic breast models for X-ray

imaging, there is still inadequate data available for MR imaging.³⁻¹⁰ Also, much uncertainty still exists as to whether the most relevant TMMs are able to sufficiently replicate the MR-related characteristics and resemblance of breast structures, especially fibroglandular tissue.¹⁶⁻¹⁹ This has been corroborated by our latest experiment using 3D-printing methods and tissue-equivalent materials to mimic the breast tissue relaxation times for MR imaging.²⁰ Notwithstanding considerable information about the role of MRI's in quantitative breast density analysis, the optimal imaging protocol and measurement method have not generally been agreed in this respect.^{21,22} This editorial summarises some of the experiment's main findings and demonstrates the utility of a personalized 3D-printed breast model for quantitative breast density assessment using MRI.

Personalized 3D-printed breast model using silicone and peanut oils for quantitative breast density assessment

3D-printed models based on patients' imaging data have allowed to learn procedures, educate students, and enhance the individual's perception of complex anatomical structures and pathologies by using such realistic reproductions. In this study, a 3D-printed breast model was developed, with the intention of providing a more precise assessment of breast density based on a realistic morphological breast structures that obtained from MR images of human-tissue. The breast examination was performed on a 1.5T MRI system (MAGNETOM Aera, Siemens, Germany) with a dedicated breast coil. Based on the recommendations from our recent systematic review and meta-analysis, the protocol for breast imaging has been selected as high-resolution, non-contrast-enhanced T1-weighted images, which assist in the distinction between non-glandular fatty tissue and glandular tissue.²¹

Overview and design

The personalized 3D-printed breast model comprises two main parts: an outer shell, which simulates the texture and form of the skin, and an inner structure, including fibroglandular and fatty tissues, which imitates the breast compositions. Firstly, the 3D skin shell and the cover have been made from polylactic acid (PLA) with the fused deposition modelling (FDM) technology.²⁰ The outer shell was printed in 0.15 mm layer height, took an average of 40 hours printing time, and had a 3.0 mm average thickness and 12.5 μm resolution (Table 1). Figure 1 shows the personalized 3D-printed breast model of the outer skin layer and sections to be filled with fibroglandular- and adipose-equivalent tissues. Then, the 3D fibroglandular models were constructed as hollow structures and have been made from photopolymer resin with the digital light processing (DLP) technology.²⁰ They were printed with 10 seconds of curing time per layer, 0.05 mm in layer

thickness, took an average of 17 hours printing time for both left- and right-models, and had a 2.0 mm average thickness and 47 μm resolution (Table 1). Figure 2 shows the fabrication of the hollow 3D-printed for both left- and right-fibroglandular models. Finally, the fibroglandular models were submerged in a fat-equivalent medium to replicate the adipose tissue's MR-related properties and T1 relaxation time. The hollow skin and fibroglandular 3D-printed models were scanned on a 3T MRI system (MAGNETOM Prisma, Siemens, Germany) to ensure neither the PLA nor the photopolymer resin produce MR signal.

Results and discussion

The T1 relaxation times of the five designated substances (agarose gel, silicone rubber with/without fish oil, silicone oil, and peanut oil) were determined on the same 3T MRI system, with the objective of simulating the MR-associated properties of the fibroglandular and adipose breast tissues. As shown in Table 2, results indicated that the silicone and peanut oils were found to be closely analogous to the T1 relaxation times and MR-associated properties of the respective tissues, which are 1515.8 ± 105.5 and 405.4 ± 15.1 ms, respectively. Consequently, those substances were selected to fill the hollow 3D-printed models. Figure 3 demonstrates a summary of the fabrication procedure of the personalized 3D-printed breast model. In a brief summary, the hollow 3D-printed fibroglandular models were filled with a silicone oil and then closed using UV-curable resin. Subsequently, the fibroglandular models were fastened inside the skin model using an acrylic-based adhesive. Next, the space between the skin shell and the fibroglandular models was filled with a peanut oil. Thereafter, the breast model was bounded with a self-constructed silicone gasket and cover. Finally, the cover was sealed using polycarbonate bolts and nuts. On completion of the construction process, the personalized 3D-printed breast model was examined on the same 3T MRI system in a prone position using a dedicated 18-channel breast coil. Interestingly, T1- and T2-weighted MR images of the personalized 3D-printed breast model using silicone and peanut oils showed that such model can be utilized as substitutes for the fibroglandular and adipose tissues, respectively. As shown in Figure 4, these selected oils in both T1- and T2-weighted images, yielded a tolerable degree of contrast and MR-associated features. Overall, the T1 relaxation times of the silicone and peanut oils used to imitate the fibroglandular and adipose breast tissues are comparable to their corresponding reference values stated in the literature.

Summary and conclusion

Personalized 3D-printed breast model based on TMMs can be used to determine the optimum MR breast-imaging protocols and measurement methods for the purpose of providing more precise assessments of breast density, thus estimating the risk of breast cancer. The developed model represents a novel approach of utilizing 3D-printing technique by further expanding its applications in the medical domain.
